The other manifestations of malarial infection in which quinine is contraindicated are as follows: (a) Fever without well defined rigor; (b) fever of slow invasion and increasing (or typhoid) temperature; (c) fever of no defined intermission; (d) a dried and concave tongue; (e) a thick, purplish tongue;

(f) a tongue with narrow strips of coating on each edge, and angry center; (g) a tongue with a narrow strip of coating in center, and thick, dark-red, almost strawberry, edge; (h) slow pulse. This last is a sign of profound infection.

The worst case of malarial fever I ever saw recover was a child ten years old. The family was wealthy, and every attention was given. His case was of the continued type. The afternoon temperature for seven days ran above 105°; the morning temperature was generally 103° to 104°. The pulse ranged from 92 to 108.

The so-called typhomalarial fever is a malarial fever in which quinine is entirely useless, save in small doses as a tonic. It is typhoid only in range of temperature. Not another symptom of typical typhoid fever is found, and the cases rarely extend over ten, twelve, or fifteen days. Rare cases are found lasting weeks, with small rise of temperature daily. The patient frequently spends only an hour or two in bed, and eats what he likes. I have seen only two cases, but both recovered.

As to infection of malaria. In the delta country (Yazoo—Mississippi River) it is dangerous to go out after dark on account of a damp fog that is seen lying along low places. I am also firmly persuaded that mosquitoes are carriers of infection.

The experience of the most successful doctors in this country is against the use of quinine in hematuria. All say that with it, used freely, almost all cases die, but without it nearly all recover. The "swamp doctors" are a unit in this, and their success certainly shakes our confidence in the quinine treatment.

In conclusion I will say that I have never seen a case of intermittent fever that would not yield to an acid solution of quinine, if a cathartic is used to begin treatment. For this I use:

- B. Hydargyri chloridi mite, grs. x;
- Podophyllin and ipecac, of each, gr. j;
- Extracti nucis vomicae, gr. ss;
- Extracti hyoscyami, grs. lv;
- Soda bicarbonatis, grs. xij.

Ft. capsule No. vj. Sig.: One hourly till two are taken, and repeat every third day.

Experientia docet. We do not use quinine in the hemorrhagic forms of malarial fever, and are now successful, whereas we were failures with quinine.

J. C. BALLARD, M.D.,
Chief Health Officer.

NATCHEZ, MISS.

INTERMEDIATE ALTITUDE FOR THE CONSUMPTIVE INVALID.*

By B. P. Anderson, M.D.,
Colorado Springs, Colorado.

The object of this paper is simply and briefly to call attention to the writer's experience during the past few years with a class of patients afflicted with pulmonary disease, such as have been recommended to and have tried both extremes of altitudes without obtaining appreciable benefit; and also to record as nearly as possible the subsequent histories of these cases.

It is to be taken for granted that the majority of the medical profession, and especially the members of this society, recognize (notwithstanding the inordinate and advocacy by individual members, enthusiastic and otherwise, of the various drug, serum, and other treatments advised for the relief of pulmonary phthisis) that the greater benefit to be expected must be from climate, and that climate alone offers the most salutary and most permanently beneficial result.

We must admit that the different climatic resorts act more or less favorably according to
the constitution, temperament, and actual condition of the individual case; also it must be admitted that in no climate with which we are at present familiar can such perfection be found as to justify the opinion that each and every case will receive the relief that is sought. No one climate can be considered as a "cure-all," the panacea for each and every individual case. No matter how honest our intention, how zealous in arriving at a proper discrimination and selection, the fact confronts us that the matter of climate is largely one of experiment, and that no man can advance a positive opinion as to the result to be derived. The reason for this is obvious. The history and nature of disease, however similar its manifestations, cannot be successfully treated and combated in any two persons by the same methods or by the same routine remedies. This more particularly holds good as to climate and its effects upon different individuals who may be suffering with the same disease. Take, for instance, two cases of pulmonary lesion, identical in every respect as to personal temperament, amount of area of disease, general symptoms, etc., and we find that the one will steadily lose ground; the disease, instead of becoming arrested or retarded, will advance. Often, if ordered to another and essentially different climate, benefit and frequently ultimate recovery will result to the failing patient.

With accumulated experience, furnishing evidence that location as to climate, altitude, etc., is the important factor as to results, manifestly it becomes necessary and of vital importance to the patient for the physician to advise changes of location for that class of cases failing to improve or become benefited.

As before stated, we admit advantages possessed by different degrees of altitude. We can only arrive at results beneficial or otherwise by individual experiences, and the progress, good or bad, of the individual case. Approximately high altitude to-day, as for the past several years, is recognized as possessing superior advantages and offering results to the average pulmonary invalid of the greatest permanent benefit. The high altitude climate of Colorado, or Colorado Springs, with which I have had experience for the past twenty-eight years, is especially adapted to and curative in the majority of incipient cases of phthisis (of whatever variety or type). Therefore we point with pardonable pride to the unchallenged fact that the reconstructed or cured invalid has been primarily the means of founding an empire, has brought his environment from that of a barren plain, or rugged, inaccessible mountain fastness, to the civilization of to-day—a densely populated region with all that goes to make the desirable in culture, refinement, and education. When we consider that the pulmonary invalid has alone brought this to pass, we can more fully appreciate the possibilities of climate as a factor in the cure of this disease. There are cases seeking this climate and altitude, however, which do not receive the expected relief. Many invalids whose physical condition, area of disease, and length of time affected would presuppose a favorable diagnosis yet find the altitude affording no relief, but on the contrary often proving disastrous. Perhaps the result cannot be traced (as many may be) to imprudence and mode of life, overindulgence in exercise, etc. My experience has been that in some of this class of cases benefit is received by change to an intermediate altitude, and for the past several years I have urged such cases to seek temporarily an altitude of from 3000 to 4000 feet above sea level, and if benefited to remain until all active symptoms disappear. Following this advice, the rule has been that such cases were enabled to return to the higher altitude of Colorado Springs, and upon the second trial improvement continued.

Experience has again taught the pertinent fact that the class of cases coming under observation which do not improve or show evidence of a subsidence of active symptoms after a residence of five to six weeks will not be benefited by longer stay, but on the contrary will continue to lose ground, and should be ordered a change at once.

In advocating the change to a lower or intermediate climate, I would be understood as meaning those cases which we term curable, or at least in which a favorable prognosis has been given. In the selection of the most favorable climate for such cases, I was largely aided by having my attention called some eight years since to the Mesilla Valley, in New Mexico, a valley situated about forty-five miles northwest of El Paso, Texas. Invalid patients coming to Colorado for the cooler summer months after having spent the winter in this valley were the first to attract my attention. Their enthusiasm as to dryness, sunshine, the greater number of days one could remain in the open air, etc., all of which advantages we have here in Colorado, did not impress me so much as did the
fact of their improvement, which could only be attributed to the advantage of altitude, which averages from 3500 to 3800 feet, combining with its lower altitude the important essential of a maximum amount of sunshine and dry air. Commencing with the fall and winter of 1892, I have regularly advised those patients who for the most part did not progress favorably in Colorado to seek this climate. Since 1892 I have a record of somewhat more than 200 cases who spent the winter months in this climate. My record embraces many cases in the various stages of advancement of disease, and many were complicated with laryngeal tuberculosis. The subsequent history of these cases shows that a large majority, or seventy per cent, improved and are still living. In the first few weeks upon making the change to the lower altitude, marked improvement was noted in every case. Active symptoms which persisted in the higher altitude subsided, and there immediately followed a gain in flesh and strength. The majority of these cases returned to Colorado for the summer months, and a few returned for shorter visits to their homes in the East. Many of these cases after having spent from one to three winters in this intermediate altitude find that a return for permanent residence in the higher altitude of Colorado is productive of no ill effects, but on the contrary continue to improve and are permanently benefited by the change. These cases upon reexamination were found to have gained complete arrest, freer expansion, greater elasticity of lung tissue, and normal respiration.

Appended tables accompany this paper, but I will not burden you with their perusal; they give maximum and minimum temperature, together with cloudy, partly cloudy, and fair days, for the years beginning with 1892 to 1899 inclusive. Patients inform me that they are enabled to remain out-of-doors the majority of days from October to May, and from the hours of 9 A.M. to 5 P.M. The disadvantages are to be found (as obtains in most cases in New Mexico) in the lack of suitable accommodations, diversion, etc.

Briefly, and I am aware not concisely, I have given my experience with a class of patients the majority of whom tried lower elevations, such as some of the southern resorts, California, etc., before coming to Colorado, but who failed to receive benefit previous to attempting the intermediate altitude.

The selection of the proper climate for the individual case is appreciated as of the greatest and first importance, and yet how difficult! It has been said long ago that the "individual result depends on the individual." No man can predict with absolute accuracy in sending a patient from home just what the result will be. I have known of apparently hopeless cases, which were advised to return to their homes with the expectation of certain death in a few months, persist in remaining, and living for years in Colorado after such advice had been given. A few years since a physician, who was then residing in Colorado Springs, and who had served on Surgeon-General Esmarch's staff during the Franco-Prussian war, walked into my office and informed me that he had been invited by a United States Army officer to accompany him overland to Fort Davis, Texas, a distance of several hundred miles. The man was apparently in the last stages of phthisis. The whole of the left lung was involved, together with the apex and to the third rib of the right. There was a large suppurating cavity in the upper lobe of the left. The physical condition was one of emaciation and prostration. I frankly told the doctor that he would not live to reach Santa Fe, one-fifth of the distance. He persisted in starting on the journey, and not only reached his destination, but improved to such an extent as to receive the appointment of acting assistant surgeon. He lived for seven or eight years afterwards, and I am informed died ultimately with some affection of the heart.

It is my belief that climate and proper environment and professional advice is the most rational, and I may say the only, remedy. If the individual finds a climate that proves efficacious in his special case, whether it be high or low altitude, that is the climate in which he should remain as long as necessary to effect recovery.

HYDROTHERAPY IN THE TREATMENT OF INSOMNIA.*

By IRWIN H. HANCE, M.D., Lakewood, New Jersey.

Insomnia, whether observed as a diseased condition unassociated with any other complaint or as an accompanying symptom of neurasthenia, is sufficiently often met with to warrant me in presenting to the members of this Society a short résumé of my past season's work. Insomnia of itself will quickly

*A paper read at the meeting of the American Climatological Society, May, 1899.
produce the neurasthenic state with its long list of vague nervous symptoms, and the physician is sooner or later forced to look for some form of treatment which will combat the two diseases. Most of us know how unreliable drugs are under such circumstances: first, because of the uncertainty of securing a definite result; and secondly, on account of the great risk run by the patient that he may contract some bad drug habit, whereby sleep is secured at the time, but the subsequent awakening brings with it the startling realization that he is the victim of one of the enslaving drugs, to escape which he must battle harder than ever man did against the evils resulting from loss of sleep.

"Sleep is a condition of physiological cerebral anemia." Insomnia, although occasionally met with as a disease sui generis, always indicates a disturbed condition of the nerve centers, and, exclusive of sleeplessness in acute diseases, is usually merely symptomatic of some other disease. In all cases there exists some disturbance of two of the chief systems of the body, the nervous and the circulatory. Therein lies the main indication for treatment—improvement of the cutaneous circulation and of the nerve cells. At the same time each case must be carefully inspected for any local cause that may produce reflex nervous conditions, and by appropriate treatment these must be lessened and eradicated if possible. In so far are drugs and a proper diet powerful agents for good, as will be shown in two of my reported cases. Bearing in mind these things, let us see how we can most surely and satisfactorily influence these bad conditions. Even in the milder forms of insomnia the most careful treatment must be pursued, since it is so very difficult to prognosticate the result in this as in all other nervous affections.

To secure the best results it is wisest for the patient to change his environment, allow himself physical and mental rest, exercise out of doors only to the point that he is not unduly fatigued, abstain from all varieties of food that produce indigestion, regulate the bowels; and the physician should examine the patient so carefully that no slight disturbance of any one of the organs escapes his attention. Having thus regulated the patient's life to the best of our ability, we must seek to restore his deranged nervous equilibrium, if possible entirely without or with the scant use of hypnotic drugs. We have at our command two agents for this purpose, water and electricity. How these are applied and with what results I shall proceed to describe by my cases, and afterwards draw a few conclusions based on personal observations.

CASE I.—Female, aged thirty-three. Simple insomnia. She occupies a position of great responsibility requiring much mental labor and executive ability. For several months past she had been sleeping less and less, until two or three hours was the limit of each night's rest. From lack of sleep she was physically weak and in a generally run down condition. A physical examination showed all the organs and functions healthy. No symptoms of neurasthenia were present. On January 11, 1899, I ordered her treatment to be a hot-air bath to perspiration, a needle spray and a general fan douche, a jet douche along the spine, followed by general static electrization (positive) with local breeze along spine. The effect of treatment was felt after the third bath. She slept longer and awoke in the morning refreshed and stronger. After twelve treatments she slept six hours each night.

On January 27 she was in New York four nights and slept badly; but the first night in Lakewood slept seven hours. I continued the treatment for two weeks more, and she left practically cured five weeks after treatment began. She has given up all work until next fall, and she reported to me two months later that the cure has been lasting.

CASE II.—Female, aged forty-five. She had no occupation, but suffered from insomnia more or less for fifteen years. For five years past she has been a distinct neurasthenic with basic headaches, scattered neuralgic pains, tenderness along spine, marked insomnia, no appetite, and a very bad circulation. Her treatment was a hot-air bath to perspiration, needle spray, general fan douche, and a jet douche along spine. She took ten treatments. Marked general improvement followed the first bath. After the third she slept well every night and gained five pounds. She stopped treatment herself because she felt that she was cured. I know she has remained well over two months.

CASE III.—Male, a lawyer aged fifty. From overwork he had gotten into an extremely bad neurasthenic state and slept only two or three hours nightly. He had an old specific history. I treated him by hydrotherapy and massage last year for a similar condition for six weeks with good result. When his stomach was examined an excess of hydrochloric
acid was found. He was treated by diet and medication in the hands of a specialist, but he lost fifteen pounds during the fall and became hypochondriacal. On December 29, 1898, the treatment was begun. Positive electrization was ordered, with hot-air bath to perspiration. A circular needle spray, general fan douche, and jet douche was applied to back. At first one to two grains of codeia used to produce sleep. After ten treatments he slept seven and a half hours without any sedative. At the end of four weeks he slept continuously six to seven and a half hours. February 3 he was discharged, averaging six hours sleep. He had gained six pounds, and his general condition was much improved. He was no longer apprehensive of the future.

Case IV.—Male, merchant, aged thirty-six; Austrian Jew. He was markedly neurasthenic, with depression and slight melancholia, and had suffered from insomnia for six months; averaged three hours sleep or less nightly. There was an excess of hydrochloric acid in his stomach secretion. On January 16 four baths were given without any effect; then positive electrization was begun and used daily with bath treatment (hot air, circular needle spray, general fan douche, and jet to back). Little effect was produced upon insomnia during first two weeks. His general nervous condition, however, improved. During the third week his sleep improved. On March 11 his gastric symptoms were noted as improved, he was resting six hours nightly, and had gained three pounds. "Hardly feels any nervousness." He now decided to continue his business, which at one time he had intended to give up in order to return to Austria.

Case V.—Male, aged thirty-eight; a priest. For ten years he had been a sufferer from insomnia. He had tried drugs, the Kneipp cure, and for three months in Adirondacks took a bath daily in cold spring water for ten minutes without friction. He was neurasthenic, with mental depression and distinct melancholia. He took ten treatments, consisting of hot-air bath, circular needle bath with hot-water jet applied to legs, general fan douche and a jet to back, and positive electrization. Out of eleven nights during which he was under treatment, he enjoyed seven good nights’ sleep, and one night slept nine and a half hours. Was obliged to discontinue treatment, and has not been heard from since.

Besides the above reported cases I have had two distinct failures, both in female melancholic neurasthenics, one of whom refused to pursue the bath treatment, and two months later developed violent melancholia. The other pursued the bath treatment alone for four weeks with slight general improvement, but with very little effect upon her insomnia.

In two patients who were treated with the electric baths and friction, followed by the circular needle bath and the general fan douche, a somnolent condition resulted from each bath, and though the patients were not suffering from insomnia their rest was more refreshing after the treatment. In some other cases where a hyperesthetic condition existed, the dry or the cold wet pack was used in place of the hot-air bath, to be followed by the douche-room treatment.

Let us for a moment consider what we accomplished by the treatment described and what deductions we are entitled to draw therefrom. By the bath treatment there is one thing that is capable of ocular demonstration to every physician and also to the patient himself, viz., an improved cutaneous circulation, as shown by an improved reaction to the eye and the loss of the sensation of cold extremities. With this surface improvement there must result a general toning up of the whole circulation and a better action of all the secretory organs of the body. The direct result of this must be a changed condition and bettering of the nerve cells throughout the cerebrospinal centers and also in the vasomotor system, whereby the symptoms which we vaguely ascribe to functional reflex disturbances become less and less, and finally lose their power for evil. We must not forget another factor, the proper application of which is almost the key-note of success in treating such cases; this is the shock to the nervous system from the change in the temperature and the pressure of the water. The stimulating effect of the shock upon the nerve centers is felt even in the simplest form of tonic baths, and by slowly increasing this through gently lowering the temperature and raising the pressure we avoid any chilling of the patient. We must secure his cooperation in the treatment thereby, and by ultimately being enabled to administer a stronger stimulus produce a more decided reaction and more lasting effect.

What part does static electricity take in the ultimate result? I can answer this best by the brief statement that during the first year of my work in hydrotherapy I had not
the means of making use of this agent, and although in two cases of distinct insomnia
with neurasthenia I finally secured a general improvement of the patient and thereby an
effect upon the sleeplessness, yet the in-
fluence upon the insomnia was slow in mani-
festing itself. During the second year by
hydrotherapy and electricity combined I
could see a distinct effect upon this condi-
tion in many cases in a few days, and in
nearly all at the end of two weeks' treatment.
I am convinced that hydrotherapy and static
electricity together are more powerful in af-
festing insomnia beneficially than either one
is individually.

With these two means it seems to me we
are justified in concluding that we are capa-
ble of so far restoring the deranged nervous
equilibrium, improving the nutrition and re-
sisting powers, toning up the circulation and
increasing the muscular power and action of
the heart, stimulating the secretory and ex-
cretory organs, that nature is capable of
adjusting the balance between the demands
upon the nervous system and the exhaustion
which must necessarily ensue from the con-
stant wear and tear of life in the business
and social world of to-day.

DANGERS OF HYDROGEN DIOXIDE IN
SURGERY.*

BY GEORGE W. SPENCER, M.D.,
Demonstrator of Surgery, Jefferson Medical College, Phila-
delphia; Assistant Chief, Surgical Clinic,
Jefferson Hospital.

My object in presenting this paper is not
to discourage the use of peroxide of hydro-
gen in all surgical cases; but I am confident
that a careful analysis of the cases of which I
am about to speak will convince you that there
are certain conditions in which peroxide of
hydrogen, if used at all, must be applied with
cautions.

My first experience of the unfavorable ac-
tion of this drug was in a case upon which I
operated through the courtesy of Prof. J.
Chalmers Da Costa. The patient suffered
with a carcinoma of the left breast with axil-
ary involvement; a considerable portion of
the skin was also affected, and, necessarily,
this was removed. After the operation it
was impossible to entirely close the wound,
and a small portion about its center was left
to heal by second intention. By the ninth
day the stitches were out and the scar was
perfect, but there remained a small place
which was healing by granulation. On the
seventeenth day following the operation the
patient was discharged from the hospital and
ordered to report to the surgical dispensary
for the treatment of exuberant granulations,
which were gradually becoming smaller.

When patient appeared at the dispensary,
three weeks after the operation, a small sinus
existed. It was about two inches in length,
and from it came a small discharge. To
keep the sinus clean peroxide of hydrogen
was injected, and this was followed by bi-
chloride of mercury. For four consecutive
days these fluids were used, and each time it
was noticed that it took more of the bichlo-
ride solution to fill the sinus than had been
necessary on the previous occasions. On her
seventh visit to the dispensary, I probed the
wound and found that the two-inch sinus had
increased to three and a half inches in length
and other sinuses were springing from it.
Shortly after this, while injecting peroxide,
I noticed a swelling which appeared almost
instantaneously beneath the axillary scar.
This enlargement was about half the size
of an egg, and, by pressing, one could hear
cracking and feel tissue crepitation. Pres-
sure caused the swelling to disappear almost
as rapidly as it had appeared. Pressure at
this point caused bubbles of gas to escape
at the opening of the sinus, which was fully
four inches from where the swelling appeared.
Tissue crepitation was not only elicited in the
axilla, but it could be induced by pressure at
several other points. Inflammation, which
was heretofore absent, now made its ap-
pearance, and soon the whole area was
nothing less than a bag of pus.

In this case there is no doubt that the
expansive force of the peroxide made new
channels and forced and deposited pyogenic
organisms into these channels from the origi-
inal two-inch sinus. After incising at several
points, draining, and discontinuing the perox-
ide, the patient made a good recovery.

While a resident in the Jefferson Hospital
I had under my care three cases which were
made considerably worse by the use of this
agent. The first case was an old woman, a
portion of whose large bowel had been re-
sected by Professor Hearn for carcinoma.
The patient rallied rapidly from the imme-
diate effects of the operation. On the fourth
day following two stitch abscesses developed
on the right side of the abdominal incision.
I incised both abscesses and syringed out the
cavities with peroxide. Previous to the injec-

*Read April 12, 1899.
tion of peroxide the inflammation was circumscribed and limited. In twenty-four hours there developed cellulitis on the right side of the abdomen, extensive and violent in character. The right side was swollen and tender, and pressure elicited crepitation; gas also could be detected in the tissues. By making forcible pressure at any fixed point, bubbles of air could be seen making their exit at the openings in the abscess cavities. In this case the gas eliminated from the peroxide seemed to travel in the subcutaneous areolar tissue, and it carried infection from the abscess cavities into the surrounding tissues.

The other cases in which trouble occurred were operated upon by Professor Montgomery. They also had stitch abscesses, and in both instances the abscesses were incised and injected with peroxide of hydrogen. The first of these two cases presented similar conditions to those we have just described; the other was quite different, and at one time the condition became alarming. In the last case the gas traveled in the planes of the muscles, and deposited between them the infectious material, producing distention, crepitation, and a profuse chocolate-colored discharge without discoloration of the skin. The odor was so foul that it became necessary to make multiple punctures, and wash out with sulphurous acid. In this case the rapidity and intensity of the process were so great that the muscular tissue seemed to become extensively necrosed, and the last case presented the clinical appearance of malignant edema.

In November, 1897, a physician from the upper part of the State was brought to Professor Keen's private hospital with symptoms of septic infection. The patient had operated upon a case of appendicitis which had been followed by general peritonitis. On the back of his right forearm were two or three scratches. Three days after the operation his arm began to swell and to pain. A physician had made two incisions, one just above and the other just below the elbow. These incisions were made to communicate. From such incisions a good deal of bloody serum, but no pus, had passed. Peroxide of hydrogen was injected. Three days after this injection Professor Keen made incisions in the forearm, and found pus in all the intermuscular planes. There were no enlarged glands in the axilla, and this seemed to prove that the infection was not traveling by the lymphatic vessels, but remained just where it had been deposited by the peroxide. Professor Keen thinks that the trouble in this case was caused by the peroxide of hydrogen.

Many members of the medical profession who work in minor surgery use peroxide as a routine practice. They seem to have perfect confidence in its safety, but I have seen a number of cases treated by this agent made worse by its injudicious use.

A few years ago, while investigating wounds of the hand, I saw not a few cases of palmar abscesses, which followed wounds of the little finger and thumb. The majority of these abscesses, it is probable, were caused by peroxide carrying infectious material through the theca of the flexor tendons and depositing it in the palm of the hand. If one considers the anatomy of the hand, it becomes evident that, by the arrangement of the two lateral portions of the palmar fascia, wounds of the little finger and thumb must be more dangerous than wounds of the other fingers, and that it is unsafe to use, in infected wounds of these members, any agent which has the power to forcibly disseminate infectious material. The lateral portions of the palmar fascia are composed of thin fibrous layers, one going to cover the muscles of the little finger, the other going to cover the muscles of the thumb. These layers practically form drainage-tubes and are continuous with the palmar and dorsal fascia. By this one can see how easily infection can be conveyed by an effervescing agent from the thumb or little finger to the dorsal or palmar surface—the path of least resistance.

In this city in June, 1897, Drs. Turnbull and Bryan presented papers to the Section on Laryngology and Otology at the forty-eighth annual meeting of the American Medical Association upon operations on the mastoid process. In the discussion on the papers Dr. Burnett said: "In the histories of all the cases reported as acute otitis media, followed by acute mastoiditis, I can read between the lines that the mastoiditis is a secondary infection, and in some cases I can see that the ear was overtreated and secondary infection followed." He also stated that he believed, in many instances, the secondary inflammation was caused by the use of peroxide of hydrogen, and that acute mastoiditis following otitis media has become much more frequent since the introduction of peroxide. He closes his views on the subject by saying that he knows no agent so efficient in forcing pyogenic germs into an inflamed ear as the expansive, energetic peroxide.

Dr. J. A. Stucky, in the same discussion,
said that he had seen many cases of acute mastoiditis caused by the use of peroxide of hydrogen in middle-ear troubles, and he considered it a dangerous remedy.

Dr. H. D. Hatch (Journal of the American Medical Association, March, 1898) said that he once had a lesson as to the explosive force of peroxide of hydrogen. In working upon a tooth his instrument slipped under the tissues almost to the eye. The wound healed and was apparently all right, but later an abscess formed well up toward the eye. There was no swelling around the eye, except at this small point, and there was no wound in the mouth. He slipped a bistoury into the abscess and injected peroxide of hydrogen. Inside of twelve hours after the injection, which had caused intense pain, the face was swollen and the eye black. He has ceased to inject peroxide into any cavity into which there is a small opening. He has had other cases where the mechanical force of the explosion gave pain. He also thinks it unwise to inject it into a bone cavity.

Janeway (American Journal of the Medical Sciences, October, 1898) reports an interesting case in which air emboli caused two attacks of temporary hemiplegia, the result of injecting a wineglassful of peroxide of hydrogen into the sac of an empyema. The sinus which led to the cavity had so far closed that no air or fluid escaped after the introduction of the peroxide.

Peroxide not only proves dangerous as an agent which is capable of carrying infection, but it possesses the power of acting mechanically in certain regions and of inducing distressing, as well as dangerous, conditions.

In 1894 I opened a deep abscess in the neck of a child. At the second dressing one of the assistants at the dispensary injected a fifteen-volume solution diluted two-thirds into the abscess cavity. At the time the solution was injected there was nothing unusual connected with the case. A few minutes later Prof. J. Chalmers Da Costa saw the patient (Prof. J. Chalmers Da Costa's book on Modern Surgery, pp. 27 and 105), and there existed then a condition of dyspnea and cyanosis. On introducing the fingers into the mouth of the patient he found a pharyngeal obstruction. The gas formed by the peroxide had worked its way down and seemed to have gotten under the mucous membrane of the pharynx and larynx, thus causing the lumen of these organs to be diminished to such an extent as to produce an impediment to the ingress and egress of air. In this case the external wound was enlarged and the peroxide was ejected by internal pressure.

The mechanical action exerted upon the tissues by this agent, during effervescence, is far greater than is supposed by many to be the case. It possesses the power to travel in relaxed tissues, along nerves, in the tendon sheaths, and in the planes of the muscles. For this reason it is unsafe to use it in infected wounds in certain locations, with or without pus, in abscess cavities either acute or chronic where the walls are supposed to be weak, in closed cavities, and in the tissues surrounding the larynx and trachea, especially in young children.

In the vast majority of cases where peroxide is used and the condition seems aggravated, I am of opinion that the cause of the trouble lies in the employment of this agent.

ORGANOTHERAPY IN GYNECOLOGY.

BY W. A. NEWMAN DORLAND, A.M., M.D.,
Instructor in Gynecology in the Philadelphia Polyclinic; Assistant Obstetrician to the Hospital of the University of Pennsylvania.

THYROID THERAPY IN GYNECOLOGY.

Of all the forms of organotherapy it will without doubt be safe to assert the marked preeminence of the extract of the thyroid gland. None of the glandular extracts have been more frequently used, and certainly none in a greater variety of pathologic conditions.

Whatever the physiologic action of the thyroid gland may be, it has long been recognized that its secretion—as also the ovarian—exerts a profound influence upon the body-metabolism, though of a directly opposite and conflicting nature. Its presence in a normal degree is essential to the maintenance of the physical equilibrium. Thus, through the investigations of the pathologists, we now know that in cretinism and its allied condition, myxedema, either this gland or its functional activity is absent; and in those cases of exophthalmic goitre in which extirpation of the gland was practiced a most alarming train of symptoms shortly developed, directly traceable to the removal from the system of the glandular influence. An excess in the normal secretion of the gland will likewise be followed by an annoying series of phenomena such as will be noted in hypertrophy of the gland or in Basedow's disease.
At once two propositions suggest themselves, namely, in cases of the first class—that is, where there is absent or deficient thyroid action—the administration of thyroid extract to supply the deficiency should be followed by an amelioration of the clinical phenomena; and in cases of the second class—that is, where there is excessive thyroid secretion—extirpation of a portion of the gland or the administration of some antagonistic extract should result favorably. These propositions were shortly tested clinically and found to be sound in theory. The administration of the various forms of thyroid extract in cases of altered or absent thyroid function is always followed by a marked improvement of the condition present, while partial thyroidectomy has frequently resulted most advantageously in the treatment of exophthalmic goitre.

To clinical experimentation based on the foregoing theory must be attributed a series of interesting and unexpected results in thyroid therapy, such as the value of its employment in gynecologic and obstetric conditions, and its undoubted usefulness in the reduction of obesity. The rationale of its employment in the latter condition has been suggested by Robert Hutchinson,* who explains its action by an increased combustion of the nitrogen-bearing substances in the body, especially of the fat, but of the muscles also to a lesser degree.

Jouin† was the first of the modern writers to call attention to the close relationship existing between the thyroid gland and the pelvic organs, although Catulle states that this relationship was well known to the ancients. In addition to the influence exerted by the uterus—especially at the time of the menopause, when the ovarian influence is dying out—upon the size of goitres, he was the first to observe a diminution in the size of a fibroid tumor under the administration of thyroid extract given to reduce obesity. He obtained a considerable amelioration, and at times even a cure, of uterine fibromata and their symptoms, and of metrorrhagia rebellious to all other conservative means. In cases of purely functional hemorrhage the results had been a complete and lasting cure; also in those of hemorrhage at the menopause or dependent on flexions, versions, and other displacements. In his hands the growth of fibrous tumors was always checked by it, and it often led to their retrogression. When it was employed early it cured them. In consideration of his results obtained in cases of this kind, as well as in the case of keloid and prostatic enlargement, he suggests that this method of therapy may be of value if applied to tumors of less advanced development, as, for example, sarcomata.

Hertoghe* has found that women deprived of the thyroid gland are subject to excessive menstrual discharges; as they grow older the menses last longer, and finally become almost a constant flow. He has also noticed that a hypertrophied thyroid is always accompanied by an early and copious mammary secretion. He has demonstrated by tests on milch cows and other animals that the secretion of milk is much increased by the ingestion of thyroid extract. From his experience he concludes that myxedematous hemorrhage is directly amenable to thyroid treatment, and also hemorrhages due to even an old endometritis or ovaritis. Cancerous hemorrhages cease after three or four days of thyroidization. The pain, swelling, and congestion also decrease to a noticeable extent. Thyroid treatment, he claims, is especially indicated in cases of frequent abortion, in which the menstrual flow is so excessive that it sweeps away the impregnated ovum. He cites an instance of a woman who was able to conceive and bear a child through the action of thyroidin after many years of sterility. Thyroidin, he finds, is also useful in cases of uterine myoma, prolapsus, or retroflexion with hemorrage, and, in general, in all cases in which it is necessary to reduce the size, sensibility, or congestion of the uterus. On account of the peculiar action of thyroidin in stimulating the lacteal secretion, it should be administered if this secretion seems to be diminishing. It has also been found that in some phases of insanity, particularly those of the puerperal, adolescent, and climacteric periods, thyroid extract seems to have marked beneficial effects.

H. B. Stehman,† of Chicago, administered thyroid tablets thrice daily to six patients exhibiting various forms of menstrual and other disturbances, including menorrhagia, metrorrhagia, amenorrhea, ovarialgia, and extreme nervousness. Each tablet represented about one-sixth of a sheep's thyroid. In each instance a most notable improve-

† American Gynecological and Obstetrical Journal February, 1897.
ment was observed within the space of several weeks. It seems conclusive, therefore, that in these cases of pelvic congestion and sexual neurasthenia thyroid extract exerts a most remarkable and beneficial effect.

M. R. Latis* believes that the thyroid juice exerts an inhibitory or vasoconstrictor power upon the pelvic genital organs, which is proved by the gradual diminution and final cessation of the menstrual flow under the prolonged use of the remedy. Menorrhagia and hemorrhages due to endometritis, ovaritis, and even cancer are greatly benefited by it.

Robert Bell† quotes the experience of various surgeons and neurologists with reference to the thyroid gland and the genital organs. He states that Charcot, having seen women affected with exophthalmic goitre cured after pregnancy, did not fail to advise marriage, on therapeutic grounds, in the treatment of this disease. Bouilly, Tuffier, Guinard, Picqué, and Bloch, having had occasion to operate on patients affected with fibroma of the uterus or salpingo-oophoritis, in whom coexisted goitres, some of which had previously resisted all treatment, have seen the thyroid tumors disappear, or at least be considerably diminished in size, after the extirpation of the pelvic organs. Bell especially emphasizes the pathologic relationship of the thyroid body to the womb and believes that the vitality of the latter may depend to a large extent on the integrity of the thyroid function. This fact especially seems to be exemplified by the marked prevalence of metrorrhagia in myxedematous conditions. He believes also that the thyroid gland especially influences the health of the skin and mucous membranes and subjacent connective tissue.

In three cases of uterine fibroids Kleinwächter‡ found that thyroid extract exerted a favorable action in controlling the hemorrhage. In these cases the intermenstrual period was also prolonged or menstruation ceased entirely for a number of weeks. It was impossible to determine any diminution in the size of the tumors.

W. M. Polk§ states that during the past two years he has employed thyroid extract in fifteen cases of fibroid tumor of the uterus. In all but one he obtained good results. In four of the cases there occurred a distinct diminution in the size of the growth. He recommends the early and long administration of the extract in daily doses of 2 ½ grains.

J. Inglis Parsons* employed thyroid extract in five cases of fibromyoma of the uterus. Four of these were women of about the age of forty years, with old hard fibromata of many years’ standing. No appreciable diminution in size followed after a three months’ course. In the fifth case, a young woman twenty-five years of age, with a large, hard, nodular fibromyoma almost filling the pelvis and dipping down into Douglas’s pouch, there occurred a distinct reduction in size. The symptoms of morning sickness and attacks of retention of urine entirely disappeared in three months’ time.

Having observed in conjunction with the good results following the employment of thyroid extract in the treatment of sporadic cretinism, myxedema, and some cases of mental feebleness, more or less marked increase in the activity of the metabolic processes of the body, Stawell† was led to believe that the same agent might be reasonably expected to increase the metabolism of the mammary gland in suitable cases. Accordingly he employed thyroid tablets (presumably each representing one grain of dried gland), given from three to five times a day, in nine cases of nursing women, and in seven of these distinct increase in the quantity and apparent improvement followed.

R. v. Braun,‡ also reasoning from the same basis of profound alteration in the body-metabolism as a result of thyroid medication, has suggested the use of the drug in obstetrics in cases of contracted pelvis in order to prevent heavy development of the fetus. He cites an instance of a woman with a funnel-shaped pelvis, protruding ischiatic spines, and an exostosis at the right iliopectineal eminence, who had been delivered by craniotomy several months previously. In her succeeding pregnancy from the beginning of the fifth month she was put on one tablet of thyroidin daily. During the first part of the remaining period of pregnancy she increased slightly in weight, and during the latter part she decreased. The fetus seemed to remain small and was allowed to go to term. She was then delivered of a 3200-gramme living

child. The previous child weighed 4000 grammes at birth. The difference in weight of the two children may or may not have been due to the thyroidin.

Cheron* holds that thyroid extract is an excellent remedy in threatened abortion with hemorrhage, and is valuable in preventing the arrest of uterine involution after childbirth, and that it is potent against the premature return of the monthly periods. Moreover, it is a valuable galactagogue. In other words, it stimulates the mammary secretion while it lessens functional activity of the uterus. In his hands it has also proved valuable in the control of all forms of uterine hemorrhage, whether this be due to endometritis, tumor, or lesions of the adnexa.

The contraindications to the employment of the drug are: tuberculosis, since this seems to be stimulated rather than arrested, and grave heart disease, where it should be administered with the utmost care, and should be discontinued at once upon the first suggestion of tachycardia. The symptoms of thyroid intoxication are tachycardia, oppression, exophthalmus, glycosuria, albuminuria, and irritability. In certain cases the drug produces rapid emaciation, and sometimes gastric vertigo will be observed.

Four cases of uterine fibromata and two cases of hemorrhagic endometritis have been treated by me during the past winter by means of thyroid extract, with the following results:

CASE I.—A. E., colored, thirty-eight years of age, gave birth to her last child twenty-two years ago. She complained of great loss of flesh during the preceding six months, associated with severe radiating pain in the lower abdomen. Examination revealed a number of fibroid nodules on the anterior uterine wall. Five-grain tablets of thyroid extract were administered thrice daily, and in one week's time she reported a marked diminution in her pelvic pain.

CASE II.—S. K., colored, aged forty-seven years, single, complained of pain in the back and right ovarian region, and a persistent though slight leucorrhoea. Her menses had never been regular, and were now profuse. Under the thyroid extract in two weeks she pronounced herself much better. The duration and quantity of the menstrual flow were greatly diminished.

CASE III.—M. M., colored, aged forty-eight years, had given birth to her last child thirty years before. She was suffering from the menopausal hot flashes, a constant leucorrhoea, and pain in the back and left ovarian region. She had a small fibroid in the posterior uterine wall. On December 3, 1898, the thyroid medication was begun, and on the 16th she stated that she was improved and the pain in her back was gone. Four days later her menses began and lasted for four days, the shortest time for years. They had formerly been profuse and persisted for from seven to ten days. The leucorrhoea was also much less in amount.

CASE IV.—L. R., colored, aged thirty-five years, single, complained of pain in the left ovarian region, frequency of micturition, and a mucopurulent leucorrhoea. Her menses occurred at three-week intervals and lasted profusely for five days. Examination showed the presence of uterine fibroids with a small mass firmly fixed in the pelvis and fibroid in nature. On September 13, 1898, the thyroid tablets were administered. One week later her pain was less and she thought she was a little better, though there was no change in the micturition. At that time the tumors seemed to be undergoing some alteration in shape, and the mass in the pelvis had become freely movable. Six days later she stated that she knew she was better than when she first came for treatment; she had less pain in the back and side. On October 6 she was feeling better generally; her menses had returned on September 27 and lasted three days. They were profuse, but no more than usual. On November 1 the tumor was decidedly smaller and freely movable. Her bleeding was not so pronounced. At her last visit, on December 6, all of her symptoms were relieved.

CASE V.—K. G., white, aged twenty-seven, married three years, and sterile, came for the relief of sterility. Her menses had been profuse from puberty, lasting for five or six days, and always clotted. In August, 1898, rapid dilatation and curettage were performed in the hope of relieving the sterility. On March 3, 1899, she returned and stated that she had been flooding for seven weeks, and was suffering from severe left ovarian pain. Examination showed a slightly enlarged endometritic uterus. The thyroid extract was administered, and in forty-eight hours the bleeding ceased and has not returned at the time of writing. The pain also had disappeared and the patient was feeling well.

---

Case VI. — E. E., a single girl, nineteen years of age, had been flooding for three weeks. The uterus was normal in size, though very sensitive. Thyroid extract in doses of 2½ grains three times daily controlled the bleeding in three days' time, and also materially lessened the amount of pain.

The following deductions would seem justifiable in the light of the foregoing reports:

1. The thyroid gland, in addition to its general effect upon the metabolism of the body, exerts an inhibitory action upon the pelvic genital organs, and upon the uterus in particular. This action seems to be especially marked upon the epithelial elements of the endometrium.

2. As a result of this inhibitory or vasoconstrictor action there follows a retardation of hemorrhages from the uterine mucosa.

3. This action is directly antagonistic to that exerted upon the uterus by the ovarian secretion.

4. In cases in which this conservative influence is deficient or absent, it may be restored by the ingestion of fresh thyroid gland or desiccations or extracts of that organ.

5. In gynecology, thyroid therapy is especially indicated in hemorrhagic affections of the uterus and in all forms of pelvic congestion, notably in uterine fibromata, hemorrhagic endometritis, menopausal hemorrhages, and chronic tubal disease.

6. The best results are to be expected in fibromata and pathologic conditions of recent development. The more chronic the case the more rebellious will it prove to thyroidization.

7. The thyroid influence is also found to cause an increase in the metabolism of the mammary gland, and the treatment is therefore indicated in all cases of insufficient lactation.

8. The drug may be administered in the form of the fresh gland substance; as a desiccated powder of the fresh gland; in tabloids of the desiccated gland; as the fresh juice; or in one of the various extracts of the gland, administered preferably in the form of tabloids. The same results may be obtained by direct transplantation of the thyroid gland from the sheep to the human subject. Because of the difficulty experienced in procuring the fresh gland and the repugnance which patients exhibit in consuming it, it is well to administer it in the dry form prepared by druggists—in tablets, pastilles, or capsules—in doses of 2½ to 5 grains three or four times daily. The average daily dose is 15 grains.

9. Owing to the tendency to thyroid intoxication it is well to discontinue the drug for a period of a week to ten days at regular intervals during the course of the treatment.

Mammary and Parotid Glands in Gynecology.

Any consideration of the subject of organotherapy in gynecology would not be complete without reference to the results obtained from the administration of the desiccated powders of the parotid and mammary glands, or of the extracts of these glands, with which I have had no experience. These drugs have been employed by others with much satisfaction in the disorders and cachexia that seem to be consequent upon the presence of fibroid tumor of the uterus and certain chronic ovarian diseases. The credit of having brought the subject to the attention of the profession must be attributed to Dr. Robert Bell, of Glasgow, and Dr. John B. Shober, of Philadelphia.

As early as 1896 Bell stated that it would appear that the parotid gland exerts a most powerful influence upon the ovaries, and that when disease exists in these organs it can be brought under subjection by the administration of the parotid glands of healthy young sheep, calves, and pigs. He further stated that it was beyond dispute that uterine fibromata, as well as hyperplasia and insufficiency of the uterus, can be most beneficially affected by the employment of the mammary glands of healthy animals. This, he said, is also true of certain diseases of the ovaries.

This form of treatment of ovarian, tubal, and uterine disease was suggested to him by the physiologic relationship which exists between these organs, as shown by mammary enlargement in pregnancy and metastasis from the parotid gland to the ovary in mumps. The effect of parotid gland upon a diseased ovary is so pronounced, especially if the uterine affection be simultaneously treated by ichthyol or other appropriate remedy, that it would be wrong, in his opinion, not to employ this remedy before resorting to operation.

In the Scottish Medical and Surgical Journal for July, 1897, Bell states that during the past two years he has obtained most favor-

*International Medical Journal, July, 1896, pp. 370-386;
British Gynaecological Journal, 1896-97, xii, pp. 157-170;
able results in over sixty cases of enlarged and painful ovaries which would certainly at one time have warranted oophorectomy. At the time of writing these women were not only perfectly well and free from pain, but also remained in possession of their ovaries. He also reported interesting cases of uterine fibromata, and uterine hemorrhages, that were either cured or remarkably benefited by the use of the elixirs of the parotid and mammary glands administered in drachm doses three times daily, or by the use of three five-grain palatinojds of the desiccated glands.

Bell reports that in cases of uterine hyperplasia there can be but little doubt that mammary gland administered in from five- to ten-grain doses three times a day has acted in a marvelously short time in promoting a speedy return to the normal condition. Menorrhagia and metrorrhagia, frequently accompanied by dysmenorrhea, have completely disappeared in the course of a few weeks, and when local treatment has simultaneously been adopted the recovery has been proportionately rapid.

John B. Shoher* reports four cases of fibroid tumor of the uterus treated with mammary gland, and four cases of ovarian disease treated with parotid gland, with excellent results. He found that in the uterine cases—the women all being under the age of thirty-five years, and therefore far removed from the menopausal influence—and without the aid of any other form of treatment, there was a steady and progressive decrease in the size of the tumor, together with a steady improvement of the general health. Under the influence of the drug menorrhagia and metrorrhagia ceased, and the menstrual periods recurred at regular intervals. He believes that the mammary gland exerts a powerful influence upon the uterine muscle or connective tissue, acting in a manner somewhat similar to ergot, and quite distinct from thyroid extract, which influences especially the epithelial elements of the endometrium.

The mammary gland has never, in Shoher’s experience, given rise to any of the unpleasant and dangerous constitutional disturbances that often follow the prolonged use of thyroid extract; it acts rather as a tonic than as a depressant to the system. The effect of the drug in checking menorrhagia and metrorrhagia induced him to use it in hemorrhages not dependent upon the presence of fibroids, and in one case of subinvolution after labor. The results were very gratifying. He employs the desiccated powder of the sheep’s mammary gland, each grain of which is equivalent to ten grains of the fresh gland. Two grains (twenty grains of the fresh gland) is made into a tablet together with three grains of excipient, and from three to four tablets are exhibited daily. In larger doses cramp-like uterine contractions are produced. Positive results may be expected in from six to eight weeks.

Shober has used parotid gland only in cases of ovaritis, in enlarged, congested, and exquisitely tender ovaries, and in cases of ovarian neuralgia and ovarian dysmenorrhea. The desiccated powder is used in the same dose and form as the mammary gland. The results he obtained by this course of treatment in selected cases were most gratifying.

THE TREATMENT OF PNEUMONIA.*

By H. A. HARK, M.D.,
Professor of Therapeutics in the Jefferson Medical College of Philadelphia.

There are two aphorisms which I am in the habit of emphasizing to my classes—one is that “when called to care for a patient through an attack of illness the physician should be a watchman all the time, and a therapist only when necessity arises.” Surely there is no disease commonly met with in which this holds true more than it does in pneumonia. The second is that in all acute infectious diseases, and particularly so in croupous pneumonia, patients may be divided into three classes, namely, those who are so mildly ill that all they need is good care and little or no active treatment, cases on the contrary so malignant that nothing can be done which will produce cure, and a third class which, lying between these two types, is capable of cure, but only when the individual is aided by the most skilful treatment.

To attempt to discuss the treatment of pneumonia without recognizing these facts is futile, for no one who has met this disease can fail to recall cases which so far as human foresight can tell were doomed from the first. My belief in the existence of a class in which

*Part of a symposium upon Pneumonia before the Section of Practice of Medicine of the American Medical Association, at Columbus.

patients will get well if let alone is confirmed by the fact that I have frequently seen them get well when treated so badly that nothing except extraordinary recuperative power could have enabled them to withstand the disease plus the efforts of the well-meaning attendant.

With these brief remarks let me pass on to a consideration of the various methods which may be employed, first prefacing what I have to say by the remark that what I have already said is not because I am pessimistic in regard to therapy in pneumonia, but because the proper way to practice medicine is to recognize one's limitations rather than to be carried away by therapeutic optimism.

Dividing the disease into three stages, what are the means we can employ in the stage of onset? No sooner do I enter this field than I am met with the question of the so-called abortive treatment by the use of bleeding or circulatory sedatives such as aconite or veratum viride. It is evident at once that at the best few patients can receive this treatment, because only a few have a sufficiently bounding circulation to justify its use, and very few are seen by the physician early enough in the malady to be benefited by it—that is, they come under observation after the acute hyperemia and congestion of onset has been followed by exudation.

Let us suppose, however, that the patient has a bounding pulse and is seen with symptoms which promise pneumonia—that is, a chill, a fever, pain in the chest, an expression of anxiety, oppression, and some cough—that his general state is sthenic, as it is apt to be in a strong, hearty man, and that auscultation reveals harsh breathing and slight impairment of resonance in one spot. Shall we resort to sedative measures, and if so, what ones?

In reply to this question my answer would be yes, employ sedatives actively and briefly. In other words, use a hot foot-bath, a hot compress over the chest where it is involved, or if the fever is high a cold compress, renewing the compress often enough to maintain its primary temperature. I would give veratum viride in three-minim doses of the tincture every fifteen minutes till three doses were given, or the patient's relaxed pulse and slightly moist skin showed its effects, and some Dover's powder to allay painful cough and increase diaphoresis. I believe at this very early period that such treatment may do much to limit the disease, or at least mitigate its severity, and I believe that eventually we may find that such treatment instituted by our forefathers and designed, to use their expression, "to break forming diseases," did break them, and perhaps did so by producing a leucocytosis or phagocytosis or development of vital activity, which further studies will reveal. Beyond the first twelve hours this treatment should not be carried out, for if not effective by that time the disease has progressed too far for such measures to do good. From this point our effort must be to guide the patient through the storm.

Before proceeding to the treatment in the developed stage of the disease, the question of the use of venesection in the early stage may be dismissed. While venesection is often valuable, later on it seems an unnecessarily rigorous treatment at this early period, and deprives the patient of valuable blood should he be exhausted by the progress of the disease. The effect of the sedatives we have named is fleeting and easily overcome by stimulants, if it is so desired, whereas the effect of bleeding is prolonged and in one sense permanent.

When the consolidation has taken place it would seem that there are four different conditions to be looked after. First, the prevention of hyperpyrexia by cold sponging with friction, the use of an ice-bag over the heart and one to the head. These local applications are of great value, I am sure. The effect of the one on the precordium is to slow the heart and perhaps to protect it from the ill effects of the fever. Certainly its use is advantageous in the majority of cases. By the use of the ice-bag to the head pain is diminished, the mind is kept clear, and temperature is to some extent controlled.

I was about to pass by the use of antipyretic drugs, because in my opinion their employment is rarely if ever of service, and when it is useful, is so by reason of their power in allaying nervousness and not because they reduce fever. In cold we have all the antipyretic power that is needed, and these drugs impair the vascular tone of the patient and decrease the activity of his blood cells.

The second indication is to aid the circulation, if it needs it. If one is worried about a patient and is tempted to give stimulants, and before doing so he feels his own pulse, he will sometimes be surprised to find that his own is the weaker, or rather the patient's heart is overworking and really needs no
stimulation, but sedation by means of the ice-bag. If the pulse does really need stimulation, what drugs shall we turn to? For years we have looked upon digitalis as the standby, but I believe it often fails because of the well known fact that it loses much of its regulating power over the heart in the presence of high fever. A number of times I have failed to get good results from its use until the fever was reduced by hydrotherapy or cold was applied locally over the heart, when it at once acted most efficiently. The question of the dose is as important as the choice of the drug itself. Surely digitalis is given wrongly in many cases, for the doses are too large and too often repeated. The drug is so slow in its effects that in pressing cases ten to twenty minims of the tincture, or one or two minims of a physiologically tested and standardized normal liquid digitalis, should be given hypodermically, and there is no necessity of repeating it for many hours, say for eight or ten or even for twenty-four hours in some cases. By giving a good-sized dose when really needed and remembering that the effect of digitalis is very prolonged, we provide cardiac support for hours and avoid producing the shuttle-like pulse of overdoses of digitalis. The next important thing is to be sure of the quality of the digitalis, for much of it is so different in effect from what it should be that the effort of the physician must be nullified by a poor drug.

If the pulse be gaseous and relaxed, bella-donna in five- to ten-minim doses every four or five hours may be useful, particularly if the skin is relaxed.

There is no drug so much employed in pneumonia as strychnine, and I think few are so often employed without good reason. Stimulants are of four classes: either they act by providing the system with material which in its combustion adds force to the body, as does alcohol, or they supply the parts called upon by their action with increased quantities of blood, as does digitalis; they liberate reserve force and enable the individual to put forth greater strength for a time, as does coca; and finally, they may act as whips or irritants to the nervous system, as does strychnine. Strychnine is therefore the only one of these which simply goads the system to increased endeavor and does not aid it simultaneously. By giving it freely when the patient seems to be sinking into the slough of death, we may rally him to a final effort to pull through, just as the crack of a whip will prevent a team from being "mired." But the skilful driver does not lash his horses all day long, and keep on lashing them after they are stalled. He uses it heroically at the crucial moment. Strychnine puts "a wire edge" on the nervous system, and if kept up causes more harm than good. For prolonged collapse or tendency thereto we may resort to coca wine. For combating a sudden collapse, strychnine is invaluable, particularly if it be combined with atropine.

It is needless to add that a fine old brandy will often agree very well with patients who have a feeble circulation, particularly if they are advanced in years.

The value of nitroglycerin in this disease seems to me to be in direct proportion to the degree of arterial tension. If this be high, this drug is of course invaluable; if it be low, it is manifestly useless, and should venous engorgement be great it is only a very indirect means of producing relief when a much better and direct means is venesection.

The value of oxygen gas is problematical. I always use it if respiration is difficult, and it nearly always seems to make the patient more comfortable, partly by the mental effect perhaps. I have never seen a patient who needed it badly who could take it himself in the sense of holding the tube to his mouth or to his nose. He has too much "luft-hunger" to aid himself, and it must be held for him.

With the treatment of the stage of resolution I shall not deal, as the discussion of this important topic has already been greatly prolonged.

I have not attempted to present an exhaustive bibliographical article, but one which is purely clinical; and in closing this symposium I cannot do better than reassert the fact already stated, that in no disease does the welfare of the patient depend more upon the skill, ability, bearing, and discretion of the physician than in this, and that nothing is more fallacious than that such cases can be treated by any routine method. The curse of therapeutics to-day is the fact that physicians do not think for themselves, but blindly follow some method seemingly valuable, so that the personal equation of the individual is lost in the sum total of the disease. No one plan can invariably be followed, for the doctor is not treating a disease but an individual afflicted by an infection which will vary in its effects according to his susceptibility and the virulence of the invading organism.
THE EVOLUTION OF MODERN THERAPY.*

BY SIMON BARUCH, M.D., NEW YORK.

Physician to Hood Wright Memorial (formerly Manhattan General) Hospital, and Consulting Physician to the Montefiore Home for Chronic Invalids.

(Continued from page 377.)

THE RISE OF MODERN THERAPY.

Being for the first time in the history of medicine clearly defined, the issue between the spoliative and constructive management of disease was now approaching decision. Many of us have witnessed this contest. Let me rapidly trace its fortunes and draw from it some deductions for our mutual benefit.

Foremost among the modern reformers in medicine stands Hufeland, who wrote a severe, arraignment of the absurdities of homoeopathy, in which he exhibits the most judicial fairness. He wrote: "Medicine is a science of experience; practice or continuous experiment on human beings, and the experiment is not yet concluded. If we have allowed the Bruonians, and if we still allow the contrastimulants, to apply opium and other heroic agents in large doses, why should not the homoeopaths have permission to use them in infinitesimals small doses? It is Nature which cures disease; art only bears its share in that it understands how to guide and aid it. It is infinitely better not to disturb this work than to confuse it by irrational and forcible measures, mislead its movements."

Krukenberg, of Halle, approached the true therapeutic ideal and served almost more than any one else in his day to advance rational treatment. He insisted that the physician should be filled with a pious regard for Nature. The organism must be taken as a whole. "Our art is undoubtedly capable of decisive action, but let it not mistake the fact that in many cases its activity is quite superfluous, in others quite void or inadequate, in many injurious. Indeed, what virtues are not assigned to one and the same remedy! When we read such commendations we seem to be actually standing in the presence of the mountebank's booth." These are words freighted with the spirit of truth, which should be taken to heart by all enthusiasts in medication!

Schoenlein, who taught in the Berlin University, was also a cautious exponent of this doctrine. Being intent upon curing rather than philosophizing, he used drugs without professing absolute faith in them, and when necessary he did not hesitate to bleed and use milder antiplhogistics.

Although the masses were still bleeding and blistering and purging, earnest protests against these spoliative practices became more frequent and more authoritative. The new Vienna school was destined to play a leading role in this propaganda. Skoda's therapeutics were pitily stated by him as follows: "Air, water, cleanliness, and temperance are the best pills. And the drug store? Well, perhaps there is some good in that, too."

Diehl wrote (1845): "Of what use is it to ascertain valvular disease of the heart with the stethoscope, the formation of tubercles by the scalpel, the diminution of blood cells by the microscope, the increase of albumin in typhoid by the test-tube? We cannot cure these diseases, and typhoid is cured more surely if we leave it to the mild care of Nature. Nature alone can heal; this is the highest fundamental law of practical medicine, to which we will be forced to adhere even when a curative principle which is subordinate to it will be discovered. This chiefest fundamental law has been misunderstood in all times. The educated physician rarely has the courage to confess it to his patient. While the physician should not promise more than he can really fulfill, he should be active at the bedside, always ready to help. A rational treatment is therefore the highest aim of the physician, and the greatest benefit which suffering humanity expects of medicine. The principal thing is not to damage the patient—Nature produces and maintains; therefore it may also cure. Among all curative powers, the curative power of Nature must be acknowledged as the highest. What she cannot do we must endeavor to do; what she is capable of doing we need not do. Another able exponent of this school appeared in Wunderlich. He opposed therapeutic nihilism as hopeless, and justly taught that although in almost all forms of disease a number of cases recover without the physician and many other cases are lost in spite of all medical effort, there yet remains a considerable number of cases in which an intelligent intercession on the part of the physician is of most positive consequence. It is a very narrow conception of professional activity to suppose that its sole object is to restore health to the sick. Shortening of suffering, removal and mitigation of discom-
fort, protection against threatening dangers, are quite as serious duties."

The teachings of the Vienna and French schools exercised a favorable influence upon the leading physicians in England and America. In England we find them represented by the great Edinburgh clinician, Hughes Bennet, who wrote: "Most diseases in vigorous constitutions, so far from having a tendency to destroy, have a marked tendency to get well of themselves, whilst instead of loss of blood, weakness, and prostration being remedies, they are sources of danger and the chief cause of a fatal result. I remember accompanying M. Louis many years ago in his visit to the Hôtel Dieu. Asking him what treatment he gave the numerous cases of severe erysipelas I saw there, he replied none at all, because they all get rapidly well of themselves in healthy constitutions. And I found it to be so. In the many cases of erysipelas in the Royal Infirmary I have never given the tincture of iron or anything else but good diet, with lotions of acetate of lead, flour or oil locally to alleviate irritation, and I have not had a fatal case. It is the book of Nature, which is open to all, that we ought to peruse and study; and why should we read it through the eyes of past ages, when the light of science was comparatively feeble and imperfect, instead of bringing all the advanced knowledge of the present time to elucidate her meaning."

In a most philosophical and logical manner Bennet attacks the prevalent practice of bleeding and mercurializing, insisting that "the real tests of successful practice are not to be sought in the alleviation of symptoms, but in the removal of disease, and that treatment is the best which, ceteris paribus, causes the fewest deaths and brings recovery in the shortest time. He states that a vigorous antiphlogistic treatment of pneumonia was followed by a mortality of one in three cases; the treatment by large doses of tartar emetic, according to Rasor, by one in five cases; moderate bleeding, according to Grisolle, resulted in a mortality of one in 6½ cases; the dietetic treatment combined with occasional small bleedings and emetics in severe cases (Skoda) gave one death in seven cases; and the purely dietetic treatment of Dietl one in thirteen cases—all being reports from large hospitals. The result of treatment directed to further the natural progress of the disease in the wards of the Royal Infirmary of Edin-

*Practice of Medicine, p. 205.

burgh under Bennet's care was one death in forty cases; there being no mortality in uncomplicated cases.

Bennet taught also that "the confident belief in mercury causing absorption of lymph is not only opposed to sound theory, but like the effect of bloodletting, it is not supported by experience. I cannot," says he, "resist the conclusion that the principles which led to an antiphlogistic practice in acute inflammations were erroneous, and are no longer in harmony with the existing state of pathology. Read the accounts of distinguished teachers and hospital practitioners as to the effects of bloodletting and compare them with what you have seen here with your own eyes of the successful treatment of inflammation. So powerful and so persistent have been the doctrines of the past that notwithstanding the facts which I made public in 1857 as to my results in treating pneumonia, and notwithstanding the fact that an antiphlogistic practice in this country is almost universally abandoned, every systematic work up to this date (1864) still recommends for that disease bloodletting, antimony, and calomel."

Here we have a true picture of the status of therapeutics in England in 1864.

These rational views percolated very slowly through the mass of the profession in America. Notwithstanding that Oliver Wendell Holmes had sent the shafts of irony into the ranks of the polypharmacists, and Bigelow had (1835) written his "Self-limitation of Diseases" and "Nature in Disease," antiphlogistic treatment continued in vogue until Austin Flint and his successor called a halt. How difficult this reformation was is evident from the severe criticisms made by the American editor of Reynolds' System of Medicine in 1879 upon the advanced therapeutics of the English author, which conclude as follows: "The intention of these remarks is not to antagonize but to qualify the summary conclusion which the language of Dr. Reynolds appears to convey, that venesection and kindred measures may with advantage be dismissed as obsolete. Of names not yet antiquated in favor of the occasional and moderate use of the lancet in the early stages of acute inflammatory disorders it may suffice to mention Aitken and B. W. Richardson of England, Niemeyer and Wunderlich in Germany, Jacquot, Herard, and Count in France, S. D. Gross and Fordyce Barker in America."

The influence of the modern Viennese school upon therapeutics had now become
quite pronounced, at least among the leading physicians of the world. Especially in acute diseases was its trust in Nature effectively applied. When, however, Virchow proclaimed in 1854 (Spec. Path. and Therap., vol. i) a deviation of temperature as the pathognomonic sign of fever, and showed that it was due to increased tissue change which in its turn is traceable to an inhibition of the heat-regulating centers by the fever-producing element, and this was supported by exact thermometric measurements, the leading clinicians of Germany sought in the reduction of this pathognomonic sign the all-important therapeutic indication. Bartels, Juergensen, Liebermeister, and others endeavored to prove that an abnormally high temperature was really the chief lethal factor in the infectious fevers, and as a logical corollary reduction of temperature was the chief aim in their treatment.* Digitalis, quinine, veratrin, cold baths, and later antipyrin and other coal-tar products were piled with might and main. At last scientific precision was in view; the thermometer demonstrated exactly the needs of the suffering system and its remedy. This doctrine spread rapidly, owing to speedy modes of communication, over the entire world. A new era seemed to dawn: antipyrinism became the watchword, which has misled the medical profession as sadly as antiphlogosis had done in former years!

When our own Welch and others showed the untenability of the excessively lethal influence of high temperature, and when the uncertain quinine and salicylic acid as antithermics were replaced by the positive antipyrin, the eyes of calm bedside observers were opened to the fallacious theory and practice. They reasoned that if high temperature was really the lethal factor, the key to the solution of the treatment of acute diseases must be found in antipyrin! But, alas, though this agent reduced high temperature with positive certainty, its influence on the mortality statistics was either negative or actually unfavorable; the only advantage attained seemed to be that antipyrin permitted the patient to die with a lower temperature.

This is the first instance in the history of medicine where a medicinal agent pointed the way to more rational treatment of disease, and was afterwards abandoned. One who has passed through the various therapeutic phases of the latter third of this century in the treatment of fevers, and who, like myself, was taught cupping, blisters, mercuryization, nauseants (nitrous powders), veratrum, and passed on to aconite, digitalis, salicylic acid, alcohol, quinine, antipyrin, cold sponging, and baths, can realize the enormous change produced by the discovery of the coal-tar antipyretics, the avidity with which they were taken up as a _magnum donum dei_, and the sad awakening when their vaunted curative action was disproved. Had this great discovery been made many centuries ago, when means of communication were meager, and methods of observation and investigation were imperfect, it would have required several centuries to demonstrate to physicians that they were pursuing an _ignis fatuus_ when they sought in reduction of temperature the patient's salvation. Happily we live in a more favored time. Not alone have the damaging effects of medicinal antipyretics upon the excretion been clearly demonstrated, but the investigation upon the subject extended to clinical studies on the comparative effect of these antipyretics and the cold bath treatment. These were made chiefly by Ernst Brand and his follower, A. Vogl, who thus discovered that the beneficial effect of the cold bath was not due to reduction of temperature, inasmuch as its antithermic power was ludicrously inferior to antipyrin. They correctly concluded, too, that the beneficent results from cold bathing in typhoid fever were really due to a refreshing stimulating effect upon a depreciated nervous system. This view had long been taught by Winternitz and other hydrotherapeutists, but had not been heeded until recent years. Thus the failure of the much lauded coal-tar antipyretics had led to the enlightened and correct treatment of fever, chiefly by cold hydriatic procedures.

THE LESSON OF HISTORY.

Fellow alumni, I have sketched for you the lights and shadows of therapeutics from the pages of history. The colors are drawn from life, for I have permitted each exponent to speak in his own words. How does this rapidly drawn sketch strike the unbiased seeker after therapeutic truths? What lessons does it inculcate? How may a more useful therapy be evolved?

---

*Wunderlich, a leader of nihilistic therapeutics, even abandoned it when the thermometric observations for which he is noted, in typhoid fever, established the danger of high temperature, and sought in infusion digitalis a panacea for this disease. Its reputation lasted three years, when one of his own pupils, Thomas, overthrew its dominion.
We are saddened by the fact that the history of our profession is darkened by somber shadows cast by each epoch. When we reflect that medicine began its career under the glorious ægis of a Hippocrates, whose insight into the true aims and possibilities of therapy has been demonstrated to have been almost inspired and prophetic, so that we must recognize the fact that even to-day our therapeutics approach perfection only in so far as they approach the ideals of our great Nestor, our hearts must be bowed with sorrow over the painful revelation that twenty centuries have passed away in argument and disputation over the treatment of disease, while suffering humanity lay prostrate, helpless victims of their errors—errors due to the neglect of the teachings of Hippocrates and to indifference to the warnings of a few brave and wise men who cried aloud in the anguish of sorrow and despair, urging a halt in the spoliation of human blood. If you accept without fear and without favor the testimony I have just cited before you, you cannot avoid this sad conclusion. Hippocrates himself with characteristic prevision foresaw it all, for he warned us that “disputes among doctors engender disrespect of the whole art among the people, so that they begin to doubt the existence of medical art. For in the treatment of acute diseases practitioners seem to disagree so much that what one declares as the best is by another thrown aside as the worst.”

Viewing the medical profession in the light of its own history, we can hardly be surprised that it has been the butt of satire from the time when Plato said that no gentleman should devote himself to medicine as a calling, to Molière and to the present day, when, as in a recent newspaper discussion on Kipling’s recovery from pneumonia, a writer was applauded who regarded pneumonia as less dangerous than the doctors who treat it.

While in the sanctity of our alma mater’s home I unburthen the sad thoughts which the contemplation of the history of therapeutics inspires, I am not oblivious to the fact that other professions are not exempt from error. Let us not therefore condemn our predecessors, who often accomplished wonders under the most inauspicious conditions, and who were misguided by false lights, their pathway not blazoned by knowledge which has since their day and generation dawned upon us. Let us rather endeavor to draw from their deeds and writings lessons that may inure to the advantage of suffering humanity, which entrusts its best interests into our frail hands.

This is the burden of my words to you today!

What are the chief errors which the history of therapeutics emphasizes?

1. The persistent effort to attack disease as an entity—an enemy which has invaded the human body and which must be driven from its stronghold. With few exceptions this idea, as I have shown, pervaded the theory and practice of all physicians so completely that even many enlightened practitioners of the present stagger under it. The disease is treated; it is attacked by the doctor with might and main. In acute cases phlegmosis among the ancients, inflammation among the moderns, demanded venesection, purgatives, emetics, and revulsives. With few exceptions the ruling idea was to weaken the enemy, to destroy him. The result was disastrous. The doctor and the disease fought the valiant fight to a finish—but too often the patient also was finished! Being the battle-ground between the contending forces, he suffered from both. If he succumbed, the disease was charged with the victory; if he survived, the remedies of the doctor received the credit. How fallacious this idea is is clearly shown by history.

Bacteriology has discovered certain microorganisms, which appear to be present in certain diseases, and great industry is displayed in searching for remedies that may be antagonistic to these under the false idea that they constitute the disease. Let the search for specifics continue, but let us not permit ourselves to be misguided by the noble ambition and continue to fight disease with antiseptics and antinemics which cannot reach the microorganisms that have entered every recess of the suffering body, and which would damage the latter, if they were capable of destroying the former.

Until other specifics are positively found, I would urge upon you not to treat the disease, but the patient.

2. Another error pointed out by medical history is the neglect of the Hippocratic teachings regarding the vis medicatrix naturæ. The sad consequences of this neglect run like a darkening shadow throughout the entire history of therapeutics. Now and then men like Erisistratus among the ancients and Hufeland and Audin-Rivière among the moderns attempted, as we have seen, to recall their colleagues from their false practices. The
regulative capacity of the human organism, which had been observed by them, had embedded itself in their minds, and they sought with all the earnestness of their natures to convey its salutary tendencies to ears which, alas, proved deaf to the most eloquent appeals. Not until the latter half of the present century do we find their warning lessons heeded. The Vienna school, led by Skoda and confirmed by the success of medicinally inert homeopathy, inaugurated a nihilistic practice, founded upon what they regarded as a scientific basis. The physician, it is true, now occupied a more dignified position; he no longer attacked disease. But he erred in the opposite, though not so destructive, direction of trusting too much to Nature. The therapeutic nihilist failed to realize that even in health he does not trust to Nature alone, but aids her by proper care in habits, removal of irritating elements, etc., and that in disease there is often even greater demand for aiding Nature in the execution of her beneficent designs. Moreover the patient, distressed by illness, was not content with the improved exactness of diagnosis nor with the more scientific attitude of his doctor. Such is suffering human nature. The sick man clamors to be cured; he not only wants to know the nature of his ailment and its probable outcome, but he demands to be placed in the best possible position to attain a pleasant and rapid recovery. The doctor cannot stand an idle spectator of Nature's process of cure; he feels himself impelled to act, to act promptly and wisely. This brings me to another error in the therapy of the past and of the present time.

3. The treatment of symptoms. The nihilistic treatment of disease introduced by Skoda and practiced by his followers did not satisfy the people, who demanded active treatment when sick. To meet this serious issue, the expectant method was evolved, which claimed for its object the treatment of disagreeable, painful, or threatening symptoms, the forestalling of dangerous enfeeblement, by timely and abundant nutrition and stimulation. Being a vast improvement upon spoliative methods, more satisfying, and really more effective than the nihilistic method, it rapidly obtained a large following in all parts of the world. It is to-day the accepted treatment of all acute and many chronic diseases. In the eagerness to satisfy the urgent demands of the patient or of the disease, the physician errs in the opposite direction when he attempts to meet every symptom. Hippocrates regarded bleeding as a valuable remedy because it relieved pain in the side, and many modern remedies have attained reputations because they relieved symptoms. Veratrum viride reduces the pulse to normal, digitalis increases its tension; antipyrin reduces temperature to normal; chloral and sulfonal produce sleep; morphine relieves pain. Besides these positive remedial agents there is a host of others, which have obtained more or less repute, through commercial propaganda or medical self-deception. Thus the materia medica has grown enormously, until to-day scarce a day passes without your receiving a circular or an agent vaunting this and that remedy for this and that symptom, and sustaining its claims by scientific and pseudo-scientific statements. The physician has learned sadly by experience the utter fallacy of these claims. He realizes that while the reduction of pulse and temperature by medicines may give temporary comfort, they are toxic agents which deprecate the vital strength. Veratrum produces collapse, morphine checks secretion, chloral enfeebles the heart, and the coal-tar antipyretics have been proven to interfere with excretion of urea. Nevertheless we need not hesitate to use the latter moderately in diseases of brief duration—to relieve muscular pains, to reduce high temperature, to produce diaphoresis. They are valuable remedies for the production of comfort in the diseases in which there is no toxemia, and even in the infectious fevers an occasional dose is comforting without being harmful.

Cold ablutions and baths have been ascertained to be less actively antithermic, but their effect being refreshing and antifebrile, they have become the favorite modern treatment for fevers. Bloodletting was used by Hippocrates for subduing pains in the side in pneumonia and allied affections. His practice was followed for 1800 years ere its harmfulness was realized. Morphine has proven equally efficacious and less harmful; hot poultices and later cold compresses soothe the pain in most cases. A milder and less damaging treatment of this symptom has thus been evolved, and yet the patient's comfort is not neglected. The routine treatment of symptoms must, however, be constantly striven against; the patient's demand for relief must be met, but not when more harm may result from following our sympathy than good from our judgment. This is the lesson of history.

4. The attempt to elevate medicine to the
rank of a science is another error emphasized by history, which clearly demonstrates that the accumulation of data and the speculation upon theories do not make a science. Medicine cannot reach beyond the limit flatteringly assigned to it by Bacon, who called it "a conjectural branch of the natural sciences." Despite the enormous mass of positive data accumulated during the latter half of the present century—i.e., during the most brilliant period of medicine—the latter still occupies the position of which Virchow wrote in his salutary editorial of the Archiv fuer Anatomie und Physiologie: "Therapeutics must rise from its empirical standpoint; cultivated by practical physicians and clinicians and combined with pathological physiology, it must be elevated into a science, which up to this time it is not." This was written fifty years ago, and it is true to-day! The reason is evident. Therapeutic problems involve so many uncertain and indefinite premises that deductions from them must be equally inexact and therefore unscientific. Nevertheless the search after positive data must continue, in order that a medical art may be constructed upon a scientific basis. Such a therapy is now in process of evolution in the modern development of the hygienic, dietetic, climatic, and hydriatic management of patients, as illustrated by typhoid fever among the acute and phthisis among the chronic maladies.

Having pointed out the therapeutic errors of the past and present, let me state as briefly as possible what I humbly conceive as the remedy. Therapeutics will not be perfected until we return to the simple teachings of Hippocrates, which have governed some of the best minds of our profession, even when their judgment was obscured by darkest ignorance of the processes of health and disease, which misled their striving after truth.

Standing in the brilliant light of latter-day physiology and pathology, aided by epoch-making discoveries in bacteriology and chemistry, and provided with instruments of precision, we are in a position to avoid the errors of the great Nestor, while striving to attain that deep insight into the processes of Nature which he taught to be the surest guide to the true art of healing.

A normal relation between the income and output of the human organism, an exact performance of work by each organ for the production of heat and labor in the maintenance of life—these represent a condition of health. They are governed by laws as inexorable as any law of Nature. The entrance of an etiological factor which disturbs these normal conditions does not suspend these laws, but directs their operation to the effort of readjusting the disturbed relations, by diminishing the work of one or more organs and increasing that of others—all with the single purpose of protecting the suffering organism against damage and death.

Ripened experience leads me to reiterate to-day what I said over a quarter of a century ago.* "As the healthy organism stands under the maternal protection of the laws of Nature, so does the disease. How else can we explain those remarkable processes, whereby health results from the chaotic and turbulent forces that violently assail the human economy?

"To these laws do we trace that vis medicatrix whose guidance we should ever seek, which arouses the whole organism to rebellion, when it is invaded by noxious agencies that endanger its integrity. Disease is not the negative of health, for the same forces which are silently evolved in the normal and peaceful action of life are aroused from their quietude by unfriendly influences. Order and law reign even where the human eye discerns only labyrinthine confusion and disorderly turmoil." Having held this view for the greater period of my professional career, I have derived more satisfaction and consolation from it than from all the books in my library. When difficulties assailed me and doubts threatened to obscure my judgment, I paraphrased Cromwell's warning, "Trust to God and keep your powder dry," into "Trust to Nature and be prepared to act."

The turbulent manifestations of disease are often but evidences of the antagonism between the action of the etiological factor and the activity of the curative factors in the organism. If the former prevail the patient succumbs or the disease becomes chronic; if the latter predominate the patient succumbs.

Rest, exercise, heat, cold, food, drink, light, air, baths, avoidance of unfavorable conditions—these are the means which unconsciously and automatically operate for the maintenance of healthy conditions. Their adaptation and utilization by the physician may restore the disturbed equilibrium in disease. Their regulation requires more judgment and skill than the prescription of medicines, because they are more flexible.

* Presidential address before the South Carolina Medical Association, 1875.
less easily applied, and less rapid in effect. They are unfortunately not so well taught and understood as is the materia medica. Do not understand me as despising the latter. Among the vast array of useless articles it contains some remedies—alas, but too few—that may be of great value, if judiciously applied, and without which I should feel myself shorn of considerable influence. It should be the chief aim, then, of the modern physician to treat the patient and not the disease, by girdling the former with strength to withstand the latter, whether it be by physiological agents, as baths, by bacteriological products, as antitoxin, or medicinal articles, as quinine, always with an eye single to the safety of the patient.

The multiplication of remedies for each disease has done much to retard the advance of therapeutics. Simplicity is the first prerequisite to precision and success.

Let me cite briefly a practical illustration of the beneficial evolution of modern therapy, which I have drawn from that familiar disease, enterocolitis, the so-called summer diarrhea of infants. Time was when this very common disease was treated as an inflammation of the bowels, with leeches, poultries, mercurials, and other antiphlogistic and spoliative measures. Later a more conservative course was adopted—laxatives, chalk mixture, opiates, and astringents being the chief remedies.

Fellow alumni, you have doubtless, like myself, experienced much anxiety and sorrow in these cases, and you have, as I often have, dreaded to encounter them. How helpless were we to save these little sufferers—how impotent even to prolong their lives! They died from marasmus or from so-called spurious hydrocephalus. I say candidly there is no disease in which I felt the inadequacy of my art so keenly as in these trying cases, until Soxhlet, Escherich, and others demonstrated them to be chiefly traceable to the ingestion and multiplication of microorganisms present in the food, which produced pathological changes analogous to those resulting from septic microorganisms. Like the latter they produce heat, redness, and swelling, with all their concomitants and sequelæ, only modified by the location and functions of the parts involved. This clearly ascertained pathological fact has led not only to the prevention of the disease by proper sterilization of the food of infants, but it also afforded a key to its management. Thorough cleansing of the affected tract, best accomplished by lavage and enterolysis, and in cases accompanied by much fever cool ablutions and baths to refresh the depreciated nervous system, have revolutionized the results in these cases. Whoever has, like myself, witnessed how these withered little creatures, with their stony gaze, parched lips, wizened faces, and panting chests, gradually sank into coma and death, while their vitality was being sapped by choleraic stools which neither astringent nor opiate could safely control, and who now sees these same sad cases quickly bloom into health and joyous child life under the modern management, must feel as grateful for living in this happy era as is the surgeon who has passed from the septic into the aseptic era of his calling.

A successful therapy has been evolved from scientific basic data. The dawn of a happier therapeutic era is upon us. Under earnest investigation of the laws of organic life, under incessant search for and recognition of errors, the evolution of therapy will go on to the end of time.

THE INDICATIONS, CONTRAINDICATIONS, AND DANGERS OF THYROID MEDICATION.

At a recent meeting of the Academy of Medicine of Paris, Francois Franck called attention to the dangers of thyroid medication, which he thought required us to be cautious in its use. He pointed out that coma, convulsions, and death may follow a massive injection of thyroid juice into an animal, and that Ewald, Langendorff, Gley, Haskover, and others have testified to these poisonous properties; while Lanz has shown that it causes excessive acceleration of the heart, and Charrin that it caused rapid emaciation. Dale-James has shown that it is possible for it to cause glycosuria. All these symptoms have been developed in the lower animals, but in man vertigo, tachycardia, pain, and great feebleness have been produced, and even death has been caused from cardiac collapse. Two such cases have been reported by Murray, one by Thomson, and one by Vernerhen. While these facts do not prevent us from using thyroid gland, Francois Franck thinks it should make us very cautious about its employment; or in other words, the fact is recognized that all remedies possessing much power cannot be abused.—Revue de Thérapeutique Médico-Chirurgical, Feb. 1, 1899.

MALARIAL NEPHRITIS.

The medical profession is gradually learn-
ing from increasing experience that in the
great majority of instances nephritis is a
secondary process set up by some diathetic
or infectious condition which may be consid-
ered its true primary cause.

The increasing knowledge which we have
obtained concerning the influence of infec-
tious diseases upon important organs, such
as the liver and kidneys and the various
lymphatic glands, has enabled us to see more
clearly that in the presence of these diseases
a number of conditions harmful to the kidney
may arise. In the first place, they are all of
them associated with more or less perversion
of the circulation of blood and lymph; again,
most of them are accompanied by more or
less marked change in the heart and in the
blood-vessels. Once more, the progress of
the disease frequently results in congestion,
and the toxic material produced directly or
indirectly by infecting microorganisms natu-
ally damages those organs most concerned
in the destruction of these toxic materials
and their elimination from the body.

In the study of the action of drugs it is the
duty of the physician not only to regard with
care the effect of the remedy upon the organs
which need its influence, but also to study
this effect upon those organs which receive it
when it is first taken and those which elimi-
nate it from the body after it has performed
its function.

So, too, in the study of infectious processes,
we should not only regard the notable lesions
produced in certain organs for which certain
microorganisms have a selective affinity, but
we should also have a broad enough vision to
recognize that the points of entry and exit
may undergo changes worthy of our consid-
eration and capable of producing grave alter-
ations in the patient's condition.

We are accustomed to recognize the fact
that scarlet fever, for example, is peculiarly
prone to produce changes in the kidneys,
that diphtheria may result in degeneration
of the nervous mechanism controlling the
heart, and that rheumatism seems to have
a particular affinity for the cardiac valves.
More recently it has been found that in a
large number of instances typhoid fever
manifests its primary effect upon the lungs
and kidneys, and in some instances may
leave the glands of Peyer or the solitary
glands of the large intestine entirely un-
touched. Further, that the bacillus of Eberth
may be found in vegetations upon the cardiac
valves, in the kidney, and in various other
portions of the body, where until recently it
was not supposed to be present. Still more
recently the belief of some of the older
clinicians that malarial infection was capable
of producing serious changes in the kidneys
has been receiving confirmation through
more accurate and scientific observations,
and the writings of Osler and Thayer at the
Johns Hopkins Hospital have done much
towards illuminating this heretofore little
understood subject. Aside from Dr. Thayer's
well known contribution upon the relation-
ship of malaria and nephritis, he has recently
read before the New York Academy of Medi-
cine another paper, in which he expresses
the view that malarial nephritis is very much
more frequent than has usually been thought,
and makes the interesting statement that the
frequency of albuminuria in the estivo-
autumnal fevers is almost as great as it is
in diphtheria, reiterating also his earlier
statement that in 768 cases of malarial fever
admitted to the Johns Hopkins Hospital,
albuminuria was present in 44.6 per cent and
renal casts in 16.4 per cent, indicating there-
fore that the albuminuria was in all cases due to congestion or other conditions in the kidney. Further than this, Dr. Thayer believed that the renal changes appear to be due to the direct result of damage to the kidneys inflicted during the elimination of toxic substances.

His paper has also brought up the question of the value of quinine in malaria, particularly in relation to nephritis and hematuria. This question was discussed in the editorial pages of the Journal of the American Medical Association many months ago, and this discussion resulted in a special editorial article in the Medical News.

It is our wish at this time to express the belief, which has also already been expressed in a recent editorial upon this subject in the columns of the Therapeutic Gazette, that no one can afford to urge the universal employment of quinine in all cases of malarial infection, whether they be hematuric or not, neither can he exclaim in favor of total abstinence from quinine in such cases. This fact is well illustrated by a case reported by Dr. Thayer, thus: A patient suffering from quartan infection suffered from a paroxysm, and under the administration of quinine the parasites disappeared from the blood for four days. At first there was a large percentage of albumin in the urine with granular, hyaline, and epithelial casts, but under the use of quinine the condition of the patient rapidly improved; although the edema disappeared the urine remained abnormal some months later, and the child died from uremic coma. The post-mortem revealed considerable interstitial nephritis.

Further, Dr. Thayer asserts that the study of his case indicates the greater frequency of nephritis in long-continued and ill-treated patients.

It is, then, our duty to remember, first, that nearly all infectious diseases exercise their malign influence upon more than one portion of the body, and in the treatment of these affections to use remedies with sufficient caution to gain all the benefit possible from their specific influence without causing at the same time damage in other parts, by reason of a collateral influence of the drug employed.

THE CONTRAINDICATIONS TO THE USE OF CERTAIN WELL KNOWN DRUGS.

In the treatment of disease it is required of the physician that he should exercise great care as to diagnosis and to the recognition of the symptoms presented which need to be relieved. It is of almost equal importance also that he should study the possible presence of conditions which will so modify the action of his remedies as to make them useless or so pervert their activities as to cause them to be harmful.

By far the most common factor to be met with in the latter respect is individual idiosyncrasy, a knowledge of which can only be obtained by careful questioning, and in some instances only by making a trial with this or that patient. Certain drugs produce effects which prevent their use in full doses in some persons with great constancy, while others seem to agree with the patient surprisingly well. While idiosyncrasy may prevent the use of any drug, certain drugs seem to be peculiarly apt to cause disagreeable manifestations even when used in great moderation. Among these quinine, iodide of potassium, opium, belladonna and its congeners, mercury, and pilocarpine occupy a prominent place.

It is not possible in this brief space to discuss all the symptoms arising from the use of quinine in the presence of idiosyncrasy. In some instances the ordinary effects of very full doses of the drug are produced by a very small quantity of it, or in other words the patient is peculiarly susceptible to the physiological action of the remedy. In still other instances these effects are so exaggerated as to hold only a slight resemblance to these ordinary symptoms, and in others the drug causes manifestations quite different in degree and kind from any physiological effect. Thus one patient may suffer from great fulness of the head with partial deafness after taking quinine, another will become entirely deaf, and a third will suffer from profuse skin lesions varying from a mild erythema to severe bullae and even pustulation. In some cases, in place of or in association with deafness, there may be temporary amblyopia or blindness. Rarely, one meets with great irritability of the stomach which is produced by quinine, or equally rarely it causes an irritable state of the bladder. All these conditions arise from personal idiosyncrasy to the remedy.

We may next consider the pathological states that produce what may be called an artificial idiosyncrasy—that is to say, the states which render the action of the drug useless or harmful. These are middle-ear disease, which is usually marked and aggravated in both subjective and objective symp-
toms by the use of quinine, since this drug causes congestion and even hemorrhage into the tympanic cavity; epilepsy, which is usually made worse by this drug; gastritis, in which state the mucous membrane of the stomach becomes irritated by this remedy; meningitis, in which the membranes of the brain are still further congested by the action of quinine; and finally irritation of the genitourinary tract in children, which is often exaggerated by the influence of the alkaloids of cinchona.

IRRIGATION OF THE BOWEL IN SUMMER DIARRHEA.

So valuable do we believe this method of treatment to be, particularly in the case of children suffering from the condition called cholera infantum, that we may be permitted to reiterate our views concerning it in this issue of the Gazette, although we are well aware that we have called attention to it editorially in previous years.

In obstinate cases, two individual things should be done for the relief of the child, namely, the use of irrigation of the large bowel by plain water, normal saline solution, or water containing a small amount of boric acid; and second, and even more important, the use of milk should be stopped for a period of twenty-four or thirty-six hours, and it should be supplanted by the use of beef juice and water to assuage thirst, to provide albuminoids, and yet at the same time to arrest the fermentation processes which are going on in the alimentary canal, and which are represented by the curds of milk which are found undigested in the stools which are passed.

Our attention is once more called to this matter by an article published by Dr. Hubbard, of Boston, in the April number of the Archives of Pediatrics. The temperature of the solution which he employed varied from 89° to 90°. The child was placed in the lithotomy position; the catheter, free from air and full of the irrigating fluid, was gently inserted into the bowel as high as possible, and the syringe held about two feet above the baby.

Ordinarily about one quart of liquid may be used, and if there seems to be any tendency to its retention, an escape tube can be inserted alongside of the entrance tube. By this means the bowel is cleansed, the temperature is lowered, the blood is sent from the congested colon to the peripheral portions of the body, and great benefit results to the child, for often a peristaltic wave is set up which cleanses the bowel even above that portion of it which is reached by the injection.

Dr. Hubbard points out that seven out of ten babies which received this method of treatment had no rise of temperature the next morning, and of fifty-two other cases not so irrigated, fifty nine per cent had a temperature. So far as we know there are no contraindications to the employment of this method of treatment, provided a fountain syringe is held sufficiently low to produce a gentle flow of liquid into the bowel, and not high enough to produce too much hydrostatic pressure, which, if it is slightly excessive, may cause griping, and if it is very excessive may cause damage.

THE VALUE OF THE TRANSFUSION OF SALT SOLUTION IN THE TREATMENT OF Puerperal ECLAMPSIA.

The Therapeutic Gazette has contained from time to time interesting editorial and progress items dealing with the value of hypodermoclysis by intravenous injections in various conditions of toxemia, and it has been pointed out that frequently life can be saved if the physician will resort to this simple, yet efficient, method of treatment.

Our attention is once more called to this matter by an article published by Dr. Allen in the American Journal of Obstetrics for May, 1899, in which he reports a series of cases which were treated in the manner mentioned. After detailing the various instances in which he employed it, he asks us to consider the advantages of this method as compared to others which are commonly employed, and then proceeds to discuss briefly the generally accepted theories in regard to the pathology of this condition.

In regard to the treatment by veratrum viride, he does not think that it is either rational or very valuable, and believes that in giving it in the full doses which are needed we are putting more poison, although of another kind, into the system of the patient. So, too, with chloroform, he does not think that it is generally an advisable remedy. Pilocarpine he naturally and justly condemns, but he believes that morphine is a useful adjuvant to chloroform.

In regard to venesection, it is evident that this method of treatment is applicable chiefly in those women who are full-blooded and extremely plethoric, and contraindicated in
those who are already anemic and lacking in blood.

Taking it all in all, Allen believes that the best treatment is as follows: In the pre-eclampsia stage, when the premonitory symptoms, consisting of epigastric pain, frontal headache, and disturbance of vision, have set in, we should thoroughly purge the bowels, stimulate the skin by warm baths, order a milk and water diet, and give nervous sedatives. At the same time the urine should be examined quantitatively to determine the amount of urea which the woman has eliminated, and if by chance this amount is scanty it should be increased by the use of diuretics, and we may add in addition by the employment of the hot pack.

When the eclampsia has already begun and delivery has been accomplished either by nature or by the aid of the physician, a hypodermic injection of morphine should be given at once, and this should be followed by forty grains of chloral and one drachm of bromide of potassium injected into the bowel. Owing to the convulsions, it is necessary to anesthetize the patient to accomplish this injection and to cause its retention, and for this purpose chloroform is by far the best anesthetic. It is absolutely necessary of course to bring on labor at once. Dr. Allen believes that a moderate amount of postpartum hemorrhage under these circumstances is advantageous, particularly if the woman has not already been bled, and also that about one and a half pints of salt solution should be injected under each mammary gland immediately after delivery, and in many cases on a number of consecutive days, in order to thoroughly wash the system of poisons. It is also advisable to keep the bowels moving actively.

The only advice which we have to add to that of Dr. Allen is that in carrying out the other important details we should not wait for delivery to be accomplished, but if possible administer the salt solution hypodermically at once, in order that it might rapidly produce its good effect. In some cases the influence of these injections is simply amazing.

THE TREATMENT OF ACUTE INTUSUSCEPTION.

As to the frequency of intussusception as a cause of acute intestinal obstruction, medical literature, especially in modern times, abundantly attests. Thus, in a total of 1652 cases of intestinal obstruction, hernia excluded, collected by Leichtenstern and Bryant, 657, or approximately forty per cent, were due to intussusception. All authors are agreed that it is most frequent in the first year of life. Out of Leichtenstern's 593 cases, 131 occurred before the age of twelve months, and the great majority of these were in the fourth, fifth, and sixth months. After the fifth year intussusception becomes comparatively rare, till the fortieth or fiftieth year, when it again increases in frequency of occurrence.

The onset of the affection is sudden; the pain is violent and intermittent. Bloody mucus is passed from the bowel, often with much straining, and there is commonly felt a tumor on abdominal palpation, which varies in size and consistency from time to time, and has an erectile or vermiciform motion. Vomiting, tympany, constitutional symptoms, and absence of fecal evacuations are common to this as to other forms of intestinal obstruction.

In infants, paroxysms of screaming and writhing, followed by intervals of repose varying from a few minutes to several hours, associated with blood-stained evacuations from the bowels, should always suggest intussusception. The palpable tumor is absent in about half the cases.

As to the treatment of acute intussusception, a clearer recognition of the admirable results to be obtained by prompt surgical intervention has in the last few years been so effective that the mortality of this at one time almost surely fatal disease is steadily dropping to about that of strangulated hernia. Martin and Hare (Fiske Fund Prize Dissertation, No. 40, 1891), as the result of a statistical and experimental study, wrote as follows:

"The pathology of the disease teaches us that disinvagination becomes more difficult in direct proportion to the length of time which has elapsed since the onset of symptoms; hence every hour diminishes the chances of success. Whatever the age of the patient or the seat of the trouble, provided the case is not of such long standing that tight adhesions have probably made reduction impossible, or strangulation has produced a partial necrosis, ether should be administered to its full surgical extent, producing complete relaxation of the muscular system; by means of a fountain syringe hot (105° to 180°) .7 per cent saline solution should be slowly (four ounces to the minute) forced into the rectum under a pressure of not over two pounds to the inch (elevation
LEADING ARTICLES.

of the irrigating bag four feet), the liquid being retained by a shoulder upon the injection pipe, readily made by wrapping it with a narrow bandage; the abdomen should be thoroughly kneaded, the manipulations being so planned as to encourage disinvagination. This treatment should continue for thirty to forty minutes, the pressure being gradually increased by raising the bag till a pressure of not over eight pounds is produced, and may, if the tumor does not disappear, be combined with inversion and shaking.

"This trial at forced reduction must be thorough and final; there should be no idea that it is to be repeated with more care and attention to detail. If it fails, the surgeon must proceed to an abdominal section for the purpose of accomplishing disinvagination."

In the last two or three years the general feeling of the profession has been to limit the amount of pressure employed in injections to not more than two pounds.

Heaton (British Medical Journal, April 22, 1899), in recording four cases of operation, with three recoveries, points out that the general mortality of the disease under all forms of treatment up to within a few years ago was as high as seventy or even eighty per cent. In endeavoring to arrive at the true mortality of the various measures employed for the relief of the disease, he collected records of 104 cases of intussusception from hospital reports. Of these, thirty-eight recovered and sixty-six died, giving a mortality of over sixty-three per cent. The abdomen was opened in fifty-five cases out of the 104, generally after failure by injection or inflation to reduce the intussusception. Because of a lack of detail in the reports, eight of these cases are excluded. Of the remainder, twenty-three were reducible at operation; eight died, and fifteen recovered, giving a mortality of 34.8 per cent. Twenty-four cases were irreducible at operation; of these twenty-two died and two recovered, giving a mortality of 91.7 per cent.

Gibson's statistics, based on 239 cases, indicate a mortality of thirty-eight per cent for the reducible cases, and of eighty-two per cent for the irreducible ones when submitted to abdominal section. These latter statistics are, however, open to the objection that they are compiled from cases reported in the journals, and hence in the main successful ones.

It is noteworthy that the disease was extremely fatal in children under one year old, the cause of death being usually shock or exhaustion. Gibson's table apparently shows that the percentage of cases in which the intestine was irreducible varied directly with the number of days of illness.

The conditions for success in treating this affection are obviously prompt diagnosis and immediate surgical intervention. The true mortality of operative cases is certainly at the present day much higher than that given either by Gibson or by Heaton. That it will soon be lowered to figures much below those given is clear to those who have followed the trend of modern writing upon this subject.

---

THE DANGERS OF DELAY.

Upon this well-worn topic there has been so much written in recent times that further insistence upon the prompt application of the most efficient therapeutics of a given disease, whether operative or not in the case, would seem unnecessary; yet it is still the almost daily experience of every surgeon to see cases of incurable disease, or of irredeemable deformity, which would have been within easy reach of complete cure but for the apparently inexplicable delay of the physicians to whose care these cases were first entrusted in applying the obvious treatment. Therefore, Robson's address upon this subject is by no means superfluous. He does not deal with the more obvious dangers of delay in surgery, such as waiting for the formation of pus before incising a felon, but considers groups of cases, in which his experience has shown him not only that delay in treatment is dangerous, but that serious delay even in these enlightened days is the rule rather than the exception. The grouping of tuberculous affections he first considers, and he holds that if complete rest were insisted on in the early stages of the joint cases, whether spine, hip, knee, elbow, or other joint, a complete and permanent recovery would occur in probably over ninety-five per cent of the cases. It is under such circumstances that the diagnosis of growing pain or rheumatism leads to a neglect of treatment until the time for complete restoration has long passed. In tuberculous peritonitis the curative effect of abdominal incision and drainage is so well attested, and the operation is one attended by such slight risk, that it should be advised before the period of extensive and irreparable degeneration has been reached. An incision only large enough to admit the finger, performed under cocaine
anesthesia, is all that is required, the procedure occupying only a few moments.

The importance of early recognition and removal of cancer has, perhaps, been insisted upon more than has early intervention in any other surgical disease. The evidence as to the complete curability of cancer by an extensive operation performed in its earliest stages is conclusive. Yet still our hospitals are filled with patients who have long passed this favorable stage.

In regard to appendicitis, Robson holds that the appendix should be removed without delay, since before suppuration, perforation, or gangrene has occurred, or before firm adhesions have formed, the operation is practically unattended by risk; moreover, it can be accomplished through a small incision, with separation rather than division of the muscular fibers.

Cholelithiasis is another condition which too often receives an expectant treatment. Many of the cases in which an ultimate and necessary operation is extremely difficult and dangerous, because performed on patients in the last stages of illness, of deep jaundice, who suffer from infected cholangiitis, persistent vomiting, or exhaustion, would, if performed at an earlier stage, have been quite simple, with the chances of recovery at ninety-nine per cent. Among the dangers of delay in these cases, not the least is that of malignant disease. Robson states that he has operated on forty cases of cancer involving the gall-bladder, or some part of the biliary apparatus, and that he must have seen quite double this number of cases where he did not advise operation. The association of gall-stones with cancer is so common that the etiological relation of lithiasis can scarcely be doubted; this, then, is an added reason for early operation for gall-stones. Robson’s views on this subject are expressed as follows:

1. Seeing that statistics from various countries and by many observers agree in showing the frequent association of gall-stones and primary cancer of the gall-bladder and liver, it is desirable that cases of cholelithiasis should be submitted to surgical treatment at an earlier stage than has hitherto been the custom.

2. In all cases of tumor of the gall-bladder, even if unaccompanied by symptoms, an operation should be advised, and the obstruction, usually a calculus, should be removed.

3. If these rules were followed, primary cancer of the gall-bladder and extension to the liver would probably be less frequent.

4. If early operation in cases of tumor of the gall-bladder were followed out, even if cancer had commenced, it could be caught in an incipient stage, when a cure by cholecystectomy, or even partial hepatectomy, might be reasonably hoped for.

5. An exploratory operation, even in a patient seriously ill, with a localized tumor in the gall-bladder region, is worth advocating, though malignant disease be feared, in the hope that the disease may be inflammatory, and so capable of relief.

6. If there are any secondary nodules in the liver, or if adjoining viscera are invaded, the operation had better be terminated as a simple exploratory one.

Robson expresses the hope that the time is not far distant when it will be more fully recognized that though cholelithiasis, so far as its course and early treatment are concerned, is distinctly a condition for medical treatment, it is both unjust to the patient and unfair to the surgeon to continue medical treatment until serious complications supervene, or the patient is almost, if not quite, past relief, before surgical treatment is advised.

In perforated gastric ulcer, at least five out of six patients can be saved by immediate operation. If a diagnosis cannot be made at once, it is much better to make a small incision in the middle line. If the gastric ulcer has perforated, an odorous gas will escape in opening the peritoneum. The opening need not be larger than just sufficient to admit the finger, and the whole exploration need not occupy more than a few minutes, it being done under cocaine, if there is objection on the patient’s part to general anesthesia. In every case where perforation is in question the surgeon should be called in without delay, and he should come prepared to operate at once if there is perforation, or to explore within twelve hours if there is doubt.

The same general procedure should be adopted in perforating typhoid ulcer. Moreover, the perforation is usually in the neighborhood of the cecum, and the seat of the disease can be reached at once by an incision there, thus avoiding the danger of a prolonged search and the exposure of the abdominal contents, so that a rapid operation can usually be done if performed early. One may reasonably hope to save about twenty-two per cent of cases of typhoid where intestinal perforation has occurred. Since from ten to twenty per cent of the fatalities in typhoid fever are from perforation, it would seem wise to call in a surgeon the moment abdominal symp-
toms occur, especially if there be pain and tenderness in the right iliac region.

Dilatation of the stomach and stricture of the pylorus are both amenable to operation, and are customarily treated for years by drugs, the effect of which is at the best simply negative. Vomiting some little time after food, with thirst, and rapid emaciation, should lead to examination for dilated stomach. If, together with the stomach splash and other well known signs, there is noted peristalsis, the chances are greatly in favor of a narrowed pylorus, which in many cases is due to some simple or removable cause.

In regard to intestinal obstruction, Robson holds that every such case should at once be subjected to surgical consultation. The surgeon should be prepared to interfere as soon as the ordinary remedies have failed, and before the system has become poisoned by the fermenting contents of the gut above the seat of obstruction. Moreover, at an early stage the diagnosis of the nature and seat of obstruction can be more easily made out. Further illustrations as to the importance of prompt intervention are drawn from ovarian and uterine tumors.

It cannot be said that Robson has advanced any new arguments or more forceful illustrations of the danger of delay in surgical practice than have been presented hundreds of times before, yet his insistence upon this point has its value. The motives of delay are, however, rapidly becoming less strongly operative, and mainly through the admirable work done by such men as Robson. Undoubtedly the chief reason for delay in calling in the services of a surgeon is dependent upon the practitioner’s mistrust of his ability to help. This mistrust dates back to the time when wounds went badly, when cancers invariably recurred, when openings of the peritoneum were almost invariably fatal, when every operation was attended by hemorrhage, and more or less marked shock. It is also accentuated by the fact that patients were too often confined to the surgeon’s care only when their condition was hopeless. The mistrust is based on ignorance of the capacity of the modern trained surgeon.

Another reason for delay is ignorance of the first principles of diagnosis. This reason is becoming rapidly less operative with the advanced standard of medical education.

Still another reason for delay is a profound belief in the *vis medicatrix naturae*, a belief fostered by the often extraordinary results following the cessation of an ill-judged system of therapeutics.

Sometimes the delay is due to the carelessness in the observation of symptoms on the part of the patient, or to a persistent concealment of such symptoms as may in the judgment of the patient be deemed by his professional adviser to require treatment at the hand of the surgeon. All these motives for delay are being steadily undermined by modern thorough medical education. It is but a few years since that the intelligent laity and doctors refrained from consulting the oculist in the majority of eye affections, because of the popular belief that these gentlemen did more harm than good. It is to be hoped that the distrust of the surgeon will pass as completely as has the lack of confidence in the ophthalmologist.

Reports on Therapeutic Progress

ON THE RELATION OF GOUT TO RHEUMATOID ARTHRITIS.

Dr. William Ewart, of London, in discussing this subject in the *Medical Press and Circular* of March 8, 1899, begins his statements as to treatment by saying that he does not intend to enter fully into a description of the treatment of gout and rheumatoid arthritis, but only so far as it bears upon the relationship between the two diseases.

In the first place, it may be stated that the treatment which is most beneficial in pure gout is that which is most detrimental for the worst cases of that form which we may term “pure” rheumatoid arthritis, to which colchicum and alkalies would be almost poison, and low living the sure means of aggravation.

The relation between the two forms of treatment is thus one of direct opposition as regards their specializations. Yet there is a considerable basis common to both. Hygiene is essential to all classes of sufferers, but specially to those afflicted with chronic ailments; and internal hygiene is more particularly needed by all sufferers from joint trouble, whether this be gout, rheumatism, or rheumatoid arthritis—in addition to the essentials of a wholesome dietary.

Our difficulties begin with the management of the mixed forms. Where the indications are not absolutely clear our action is of necessity somewhat tentative. In most of the cases to which reference has been made there is, besides the rheumatoid basis, a suspicion
of the gouty element. Dr. Ewart believes that in many of these cases the best treatment is to treat the rheumatoid arthritis as thoroughly as this may be wisely done, and to be sparing with the more energetic remedies for gout. Our most important duty seems to be not to add in the slightest way to the depressing conditions under which the rheumatoid patient is suffering. A relatively lesser evil would be to temporarily increase his gout. But even this need not occur if our treatment be happily conceived.

There is one direction in which the treatment of both affections can be carried out with safety and benefit almost irrespective of their special characters—that is, the local measures of relief to the joint. We are now provided with additional means, and most effectual ones, of local treatment. It had been long noticed that the old-fashioned balnear treatment, which is often most serviceable in gout, led to very imperfect and often detrimental results in rheumatoid arthritis—that is, the treatment of the patient by prolonged immersion in a hot bath. The same debilitating effect would result in some of the mixed varieties of rheumatoid arthritis in spite of their gouty complication. The general balnear treatment had of late years been abandoned in all such cases for the more local measures of steaming, hot douching, and massage, applied more especially to the joints affected, and our chief success had hitherto been derived from this method. We are now provided with various means of treating the joint affected by dry heat up to a very high temperature. The careful application of these new methods graduated to each case will enable us to feel that a great deal is done for the joint, whilst no possible harm is suffered by the patient, whatever be the stage of his articulor complaint.

Dr. Levison, in a most interesting article, has provided us with suggestions as to the diagnosis between rheumatoid arthritis and gout by the x-rays, and as to the treatment of the gouty joint by the electrolytic method. Thus electricity, which has been long known to be of considerable use, whether in the shape of the electric bath or of the constant current directly applied to the limb in cases of rheumatoid arthritis, has now found a yet more direct application in gout, since it addresses itself to the removal of the material which is the source of local irritation and pain.

Meanwhile the internal treatment of such cases may be carried out on lines conformable not only to some of the obvious indications, but also to theories which are in some respects divergent. The abundant use of water as the means of accelerating excretion of waste products and of all forms of toxins, and assiduous attention to the activity of the bowels, are equally desirable in gout and in rheumatoid arthritis, and fulfil the indications claimed by the neural as well as by the humoral theory.

In mixed cases occurring in mature age it may be best not to complicate the position by any vigorous tonic treatment, nor even by the iodide of iron, which has found so much favor since first advocated by Sir A. Garrod, and which is admirably suited to the uncomplicated form witnessed in children and young adults. There may nevertheless be room for the administration of arsenic in small doses and of sulphur, in addition to the purgatives. These have also been largely prescribed by the same authority before the more recent ideas concerning the septic origin of rheumatoid arthritis had been set forth. It may be said for arsenic that in addition to its antiseptic properties, it must approve itself to those who regard arthritis deformans as conditioned largely by a disordered nervous function.

Those are some of the general lines upon which doubtful cases may be treated safely, and with the promise of much benefit.

Reference has been made to the acute and painful forms of rheumatoid arthritis, frequently monarticular, in which an inherited gouty proclivity or an acquired tendency to gout may be a factor. As previously suggested, treatment comes to the aid of diagnosis in these cases so apt to puzzle us. Antirheumatic remedies and methods of treatment are absolutely harmful, and there is a positive intolerance—though this is not always thought of by those in charge, nor even often realized by the patients themselves—for the ordinary heat of the rheumatic bed. Let this influence be removed and they are immediately benefited. Dr. Ewart regards this variety of complaint, long ago described as an affection sui generis and successfully treated by Dr. Fuller, as a special form of rheumatoid arthritis, of a vasomotor type; and in treating it he is impressed with the necessity of addressing the treatment to the vasomotor system. The best way to do this is the application of heat or cold. Whilst we had remained restricted to the former methods of
thermal treatment, treatment by heat had often failed, and the application of cold had been found to be the only successful method in some cases, after trying in vain the use of hot spongings or even of the hot-air bath. Now that different methods are available it is conceivable that cases of this kind, although refractory to ordinary heat, may be relieved by the heat cure and derive great advantage from the high temperatures generated by electricity and by other means, as they certainly do from cold applied locally.

As regards the general and medicinal treatment of this variety, it must vary with the individual characteristics of the patient, but in the average case most advantage would be gained by our disregarding indications derived from a mistaken diagnosis of rheumatism, and by our not being deterred by the gouty family history or personal antecedents from endeavoring to raise the general strength of the patient. This practical view would also meet the indications suggested by any toxic theory which might be entertained by some in preference to the neural vasomotor theory.

The antiseptic treatment by the internal administration of creosotes, phenols, and naphthols, recommended by Bannatyne, and the local germicidal intra-articular treatment by means of iodoform, carbolic acid, and other germicides practiced by Max Schüller, are too important to be passed altogether unnoticed, but they are specially intended for the infective form of the disease, and they have not, so far as the author knows, a direct bearing upon the subject of this discussion.

Lastly, we come to the question of diet and of alcohol, the answer to which is foreshadowed in Dr. Ewart's preceding remarks. The rheumatoid patient needs, above all, to be fed, and wine suits him well; but if he should turn gouty we cannot disregard his gout. It is preeminently in this connection that the practical purpose of this discussion is revealed. How to diet the patient and whether or not to allow him alcoholic stimulation are points not to be safely decided except on the strength of an accurate diagnosis, not only of the general character of the case, but of its special phase. In doubtful cases there is probably more rheumatoid arthritis about the patient than gout, and Dr. Ewart is in favor of the policy which he has indicated in his remarks on treatment, of running the risk of a slight gouty exacerbation rather than of incurring the reproach of intensifying the depression and debility inseparable from the rheumatoid state. The gouty element, if present, may however restrict the choice of stimulants to those more suited to gout; whereas in uncomplicated rheumatoid arthritis, particularly that of the young, the prevailing anemia calls for a supply of the red wines. In both cases the delicacy of the digestion has always to be borne in mind, and it is equally essential that the diet should be easily digestible, and that it should be sufficiently varied and nutritious.

TREATMENT IN THE EARLY STAGES OF ACUTE APPENDICITIS BY SALINE APERIENTS.

The treatment Dr. Maylard proposes, in the Glasgow Medical Journal for March, 1899, in the early stages of acute appendicitis is as follows:

1. Give copious warm soap and water enemata.
2. Administer hourly until the bowels move freely small teaspoonfuls of sulphate of magnesium dissolved in about two wineglassfuls of warm water.
3. Apply hot linseed poultices to the right iliac fossa.
4. Feed on whey, chicken, tea, meat jellies, etc.

THE INDICATIONS FOR CHLOROFORM DURING LABOR.

Under this title Bacon, of St. Paul, writes a paper in the Northwestern Lancet of March 15, 1899. He points out that the sanguine diathesis gives us patients who are usually large and florid, with muscles that are well developed. Arterial tension is high, and as age advances the heart has a tendency to hypertrophy and to fatty degeneration, and the muscles become inelastic. Young patients of this diathesis bear chloroform well, but it should be used less freely as age advances, unless hypertrophy of the heart and weakened blood-vessels are present.

Strumous patients are defective in nutrition; the bones are frequently irregular; they have little or no adipose tissue and are irritable, with weak muscles. A few drops of chloroform at infrequent intervals and during a pain will give these patients much comfort. Fortunately the fetus is usually small, and the few drops necessary to relieve irritability will not increase the duration of labor.

Dark, despondent women of the bilious diathesis are slender; their tissues are dry
and inelastic; they are inclined to be whining, with little fortitude in pain. In these cases begin chloroform early in small regular amounts, and the patient will soon become courageous and patient and will eagerly follow instructions and assist the uterine contractions. These patients will insist that chloroform increases the strength of their pains, and the change in their demeanor will seem to corroborate their statement. The bilious frequently merges into the sanguine, and we have large, steady, persistent people with marked tendency during labor to rigid os and perineum. When the bilious merges into the nervous diathesis, we find active women but great sufferers. We find many of our chronic invalids of this type. Both of these classes are benefited by the use of chloroform from the early stages of labor until the end; even small regular amounts, sufficient to relax spasmodic muscular action and relieve keen pain.

The bilious and lymphatic combination presents to us a helpless creature whose natural weakness is intensified by despondency. She has heard that chloroform makes her labor easy, and she insists upon having it, and having it early and in large quantities. To refuse is to add panic to fright, but the difficulty is readily overcome by liberal inhalations of alcohol. Chloroform should not be administered in normal labors with this type.

The sanguine diathesis is frequently blended with the nervous and bears chloroform well. When the strumous is blended with the nervous, chloroform can be used freely. When the strumous is merged into the sanguine chloroform can be exhibited freely, but should be watched more closely than in the nervous diathesis.

When valvular lesions of the heart are present, the increase in the volume of blood and the increased engorgement of the vessels that occur during the uterine contractions become a source of danger. Without chloroform the heart’s action becomes labored and irregular and the patient’s distress is great, but immediately upon its exhibition the vasomotor dilatation allows the patient to bleed into her venous system and the vigor of the uterine contractions is lessened. The excess of work thrown upon the heart is removed, and the relief to the patient is so evident that Bacon would as soon think of approaching one of these cases without aseptic precautions as without chloroform.

When disease of the blood-vessels is present chloroform should be administered to relieve straining and lessen the danger of rupture.

Albuminuria is benefited even though eclampsia is not present, when the albumin is due to reflex irritation or increased arterial tension, and under its influence certain French and German investigators claim that the amount of albumin excreted is diminished and sometimes disappears.

When eclampsia occurs before delivery the convulsions are controlled, the exhaustion and the danger to the heart and blood-vessels are averted, and the uterine spasms are checked, allowing normal contractions to occur.

In certain cases the pain is of such a character that labor is delayed, and chloroform at such times hastens delivery and prevents some dangers.

In primipare when pains are severe and the os dilates slowly, the patient becomes worried and weary and nervous irritability and exhaustion follow.

It sometimes happens that intense suffering inhibits proper contractions, and inefficient pains result.

In abnormal uterine contractions pain sometimes becomes pathological in intensity, as seen frequently in hysterical women.

During the second stage, particularly if it is long continued, the vulva becomes swollen and irritable, and if the pains are severe the patient frequently cannot be induced to strain.

In all of these cases chloroform given to the obstetric degree takes the edge off from the pains and gives the patient courage; at the same time the intervals between pains are lengthened and the patient obtains rest. Chloroform should be used to control tetanus of the uterus, spasms of the cervix, and to relax a rigid perineum if due to reflex irritation, but it should be borne in mind that a rigid perineum is frequently but an indication of weakened uterine action. In precipitate labor, if the rigid condition of any portion of the birth canal makes tearing probable, chloroform should be administered in quantities to lessen uterine force as well as to relieve pain.

Forceps are applied usually because of uterine inertia, and chloroform should be used to relieve sensibility and allay reflexes, but the tendency to flood should be borne in mind and its use discontinued before delivery.

During version, anesthesia is required for all sensitive patients. Without it the uterine
muscles become tense as the hand pushes in, and sometimes the contraction becomes continuous; besides, the pain is intense and struggling frequently interferes with the necessary manipulation. It should be discontinued as soon as turning is accomplished.

It should be omitted only when the abdominal and uterine muscles are insensitive and when the cervix is dilated and flabby or when contraindicated by disease. Chloroform is useful in all cases where it is necessary to pass the hand into the uterus to change presentations.

In foot and breech presentations it is useful in unruly patients, but in the main the benefit as an anesthetic is doubtful, for the cooperation of the patient and the uterine pains are necessary assistants.

In all surgical procedures during labor chloroform should be used upon the same indications which govern its use in other cases.

ANTISTREPTOCOCCIC SERUM IN THE TREATMENT OF Puerperal Septicemia, Septic Cellulitis, Postoperative Septis, and Erysipelas.

ROBINSON writes in the Virginia Medical Semi-Monthly of March 10, 1899, of his experience with this serum. After detailing his cases he says it will be noted that with the exception of three cases of the puerperal class, the attacks came on within three days following delivery. Such a history points strongly to the streptococcus as the cause of the septicemia. When there is profuse discharge we may suspect sapremia; still there is often a mixed infection, and we need not hesitate to use the antistreptococccic serum for both the possible benefit and the diagnostic advantage. The results in the puerperal cases are strongly suggestive.

The postoperative cases were no less striking in their response to the serum. The septic cellulitis cases and the gunshot wound demonstrated the value sufficiently positively to encourage further trial.

The erysipelias cases were too positive to be questioned. Dr. Robinson says he grants, from a strict scientific standpoint, that his report may have little significance to microscopic investigators, but to the great body of busy practitioners whose souls are deeply stirred by these perplexing cases, and who have no microscopical advantages or conveniences, the antistreptococccic serum will be most gladly welcomed.

Touching the doubt of all things, without microscopic proof, he says it appears criminal to bar the profession from the use of a remedy pregnant with such possibilities of relief.

In all save his first case Parke, Davis & Co.'s serum was used.

REMARKS ON THE DESIRABILITY OF A MORE CAREFUL STUDY AND EXTENDED USE OF HYDRO- THERAPEUTICS.

DR. PUTNAM, the well known neurologist of Boston, asks the following question in the Boston Medical and Surgical Journal of March 9, 1899: Is a "shock," from a sudden application of cold water, useful or objectionable? The latter view is often maintained, both by patients and physicians, but the former is correct, provided only that the shock is proportioned to the habits and the capacity for reaction. Patients are apt to dislike the "shock" of cold water, and if they are feeble or nervous it may, if severe, frighten or fatigue them. For this reason, when an unfamiliar method is first used the application should be as warm as 85° to 90°. This will feel cold if the skin has previously been warmed to 100° or higher. On the other hand, the common practice of letting cold water run gradually into a previously hot bath, so that the temperature is slowly lowered and "shock" avoided, is an objectionable one, and much less likely to be followed by a good reaction than a more sudden change, especially if the latter is associated with smart friction, as in the case of the drip-sheet or forcible cold affusion given by another person. It is not easy for a patient to make a thoroughly satisfactory cold application unaided except by an immersion bath, since otherwise, at the best, only half the body can be bathed and rubbed at one time. The immersion bath at low enough temperatures to be thoroughly stimulating is very refreshing to vigorous persons who are thoroughly habituated to it, but less safe for feeble persons. If the latter must take their bath unaided, rubbing with a large, dripping-wet towel is perhaps the best method.

Hot baths, at temperatures considerably above that of the body, have primary effects similar to those exerted by cold baths, but secondary reactions are liable to occur, leaving the skin pale and cool and the arter
tone low, and, moreover, the skin is for a time after them abnormally sensitive to slight cold. It is risky, on these accounts, to take hot baths at bedtime, because the primary heat of the skin leads the patient to underestimate the amount of clothing which will be required later, and he may wake to find himself chilled.

These dangers are diminished if sufficient time is taken to allow of complete cooling before going to bed, or if the hot bath is followed by a dashing or rubbing with cold water. Of course there are cases, however, where the sedative action of a prolonged warm bath is very useful. Massage given during warm baths is useful for elderly people with arteriosclerosis (Jacobi).

It is a mistake to suppose that shivering is necessarily a sign that the body is becoming chilled to an objectionable degree. Shivering frequently occurs when one rises from bed on a cold morning, and yet wholly disappears, together with the sense of coldness that accompanies it, after a plunge into very cold water. Even blueness of the finger-tips is not necessarily a danger sign, since it is usually due to local changes in the cutaneous circulation and not to weakness of the heart.

Children do not require as low temperature as adults to develop such a degree of reaction as can be expected from them, and do not stand severe cold as well.

Where the reaction on the part of the vaso-motor system is to be limited to a small portion of the body, lower temperatures and more prolonged application can be used than where the whole surface of the body is to be exposed.

Where drip-sheets, or sheet-baths, or wet packs are to be used, coarse linen sheets or damask table-cloths are better than cotton sheets, as being more absorbent and affording better surfaces for friction.

The mechanical impact of a stream of water delivered under high pressure in the form of a douche adds greatly to the stimulant effect, and insures a better reaction. Nevertheless, a feeble patient has to be accustomed gradually to high pressures as to low temperatures, and at first relatively short applications are necessary. In a well-appointed institution greater and readier variability, and thus better results, can be obtained than in a private house.

Especially necessary is in applying baths tending to produce much reaction, to elderly persons, or to any person with brittle arteries or with disease of the heart. In the discussion that followed Dr. Coggeshall said it had always struck him, in watching the advantage which prominent men, of the class who are our consulting physicians, have over the general practitioner, that it was quite as much in the wider range of their resources in therapeutics as in their superior ability in diagnosis, and it seemed to him that one of the greatest difficulties that the general practitioner labors under is that he has very few medical resources beyond drugs, and that he is apparently unconscious—almost unconscious—of the wide applicability of other means of treatment. Drugs and surgical operations are the widest range of his therapeutic imagination, and if we are to get the best results with a great many forms of chronic diseases especially, and he thought also with a great many acute diseases, it seemed to him that we ought to pay more attention to other means of treatment, and among those in his short experience he had seen none he should attach more importance to than hydrotherapy. It is commonly thought of as a process of giving people baths, and that there is a difference of temperature. We may give a hot bath or a cold bath; but any one who has studied the work of Baruch in New York or Wintenitz in Vienna, and many other eminent men in Germany and other parts of Europe, must realize that hydrotherapy is a much more complicated subject than the mere question of giving a bath and giving a bath hot or cold. If physicians did realize the amount of benefit that accrues in a wide variety of cases from water treatment in various forms, they would take more interest in it. The objections to it with the general practitioner are of course obvious and serious. It would take a great deal of time to study the details of treatment. It would be like having to learn a whole materia medica over again almost, and it requires more time to plan the treatment for an individual case than to write the most carefully considered prescription; and yet he said he could not help believing, from what he saw abroad, and what little opportunities he has had for personal experience since he has been in practice, that the results would repay the additional time and trouble which the careful carrying out of such treatment would require. Then there is the expense, which is, for the finer details of such treatment, out of the question for the vast majority of private patients. He had been able in the case of one private patient to get him to put into the house some of the appliances re-
required for that case, and he said the patient has always felt since that, although he expended some hundreds of dollars on them, he got better money's worth out of it than out of his physician's prescriptions. That, however, would be a very exceptional case.

The only way in which we can carry this treatment out successfully would be to get an institution which would undertake to provide all the apparatus required for the complete system of hydrotherapy and carry out the treatment of cases under the direction of physicians, perhaps with the assistance of consultation advice as to the treatment in the case from some one who had had a large experience in that kind of therapeutics.

Dr. Coggeshall said another reason why an institution would be an important, in fact an absolute, necessity to any general use of it would be that it requires skilled assistants to apply the treatment. He had found some very disappointing results in attempting to carry it out in private families, even with the simple forms of baths and giving the most minute directions he could to members of the family. A nurse must superintend and apply the treatment throughout; and he does not think it is very easy for the patients to do it for themselves, even after they have been under the treatment some time, because one constantly wants to alter the details of the treatment in the same case.

The diseases in which Coggeshall has seen the treatment effect most good were among nervous diseases—hysteria and neurasthenia, in both of which the results appear to be excellent. Among the commoner diseases that in general practice he should think it was most valuable in, for one he mentioned many cases of organic diseases of the heart. He began to use this treatment for diseases of the heart about three years ago, and tried it on the first case with a good deal of hesitation. Now, with the great majority of cases of valvular disease of the heart he sees, he uses it with a great deal of confidence, and generally the results have justified that confidence. He is sure that every case of simple dilatation of the heart is benefited by it, and cases at least of mitral disease have seemed to him, in the comparatively few he has had an opportunity to try it in, to be excellently adapted to it. In the case of the Schott treatment, of course, it includes exercise. Dr. Coggeshall had tried the exercise without the baths in a number of cases, and although he got benefit, he got much less benefit than in the cases in private practice that could afford to have a nurse come to the house and give them the baths as well as the exercise; and in one case, in which he tried the baths alone, he thought he got as good results as in the baths and exercises combined.

In acute diseases the use of baths in typhoid, of course, is familiar to all of us. He thought there was a wide divergence of opinion among physicians who have tried them, as to the benefit, and it seemed to him that a good deal of that divergence was due to the fact that the details of the treatment had not been carefully carried out. He said he remembers visiting a large hospital some years ago in which the visiting physician told him they were using the Brand treatment for typhoid fever, and he said it in rather a skeptical way, which implied that he did not get many results from it and did not expect to. Dr. Coggeshall found he was giving the baths by sponging the patients in bed. That is not Brand's treatment. It is an illustration of the laxness as to the details with which experiments in such treatment are often made. He did not get very good results, and it is thought the treatment was abandoned as the result of experiments which consisted entirely of sponging the patients with cold water. Dr. Coggeshall said he has had very little personal experience in the treatment of typhoid fever with it, but he has had experience in the treatment of two conditions occurring in acute disease which gave him a great deal of confidence in the value of simple cold bathing in such cases, and that is in the matter of convulsions occurring in children in connection with any severe or light disease, and in the treatment of delirium. The effect in delirium in pneumonia or typhoid fever has been, as he has seen it, certainly more marked than any other treatment he has ever seen attempted for it; and in convulsions of children, even in hopeless diseases like tubercular cerebrospinal meningitis, certainly the relief to the symptoms and the greater quieting, the rest, the improved action of the heart which he got from suppressing the convulsions with the cold bath, were well worth the trouble of giving it. Of course, in such cases as this, and in a case of delirium occurring in pneumonia, he found the greatest difficulty in persuading the family that the patient would not be killed by immersing him in water as cold as he wished to put him into. He had tried it in a number of cases, and had not seen any bad results.
Dr. Coggeshall supposed it was fair to class under the water treatment the application of ice-bags to the chest in pneumonia and bronchitis. That is another form of treatment he had used repeatedly, and always, it seemed to him, with some or a good deal of benefit; but if we are to get satisfactory results in such cases as those spoken of, whether in the chronic forms of diseases like hysteria and neurasthenia, or in the treatment of delirium and convulsions occurring in acute diseases, we must attend to the minutiae of the treatment, and until we do so he thought it was not fair to draw inferences from the results. Dr. Putnam mentioned some examples of fallacies involved in reasoning about the treatment, and Dr. Coggeshall wished to mention one or two others.

He believed Dr. Putnam mentioned the fact that the temperature was not much lowered by short cold baths, and Baruch, he thought, was the first who called attention to the fact that although the temperature as taken in the mouth was lower the temperature in the rectum was not materially affected. Some physicians, in thinking of the application of cold bathing to typhoid fever, have apparently assumed that the principal value of it was as an antipyretic, and that it had the same use as acetanilid or phenacetine, except that it might be less depressing. Dr. Coggeshall said he could not believe that that was its value; in fact, as he had tried it, in cases of typhoid fever, he had found there was perhaps one-half degree fall in the rectum, although there might be a marked fall in the mouth; and he had always regarded the rectal temperature as the true indication of the fall, and the mouth temperature as a side issue, to which he did not attach particular importance. He never valued it because he thought it would lower the temperature, but because of its effects on the central nervous system and through that upon the circulation. He believed that was the true value of it in such cases, and if it did act as a nervous stimulant, if it was energetic and lasting in its effects, it was of much more significance than the mere effect on the temperature.

As illustrations of the importance of attention to detail, the speaker said he could give examples of the way in which it is often laid down in the books, that baths should be given at such and such temperature, etc., and if this is carried out by physicians who have not used it much, exactly on these lines without reference to the marked difference we find among patients in their powers of reaction, the method will fail. Two cases will differ very much in the way they will react to treatment; and the details of the packs, the douches, or whatever is being used in the case, ought to be worked out by carefully feeling one's way with regard to that individual patient. Where the reaction was not good he had never hesitated in any form of acute disease to use alcoholic stimulants before the baths, and he would always do that rather than abandon the baths in such cases; and he had found that hot whiskey and water or brandy and water before the bath obviated entirely the unpleasant effect in such cases.

One other illustration of the importance of detail he said he should like to mention was in the method of giving the baths when the patient is not in the tub—the so-called sponge baths. It had always seemed to him that the sponge was the poorest thing that could be used. We cannot get friction from it, and it is cold in a disagreeable way. It is more apt to chill the patient, whereas if rough bathing gloves were used and the cold water rubbed on the patient, instead of being stopped on with a sponge, the effect would be markedly different. One very important factor is the pressure under which the douche or spray is applied, which is independent of the matter of temperature, and that is another thing that makes it in private houses almost impossible to secure the results that can be secured in an institution suited for the purpose.

THE PRINCIPAL DIURETIC MEDICAMENTS.

Martz, of the Faculty of Medicine in Lyons, gives a number of prescriptions for diuretic purposes. Pills composed as follows:

Extract of convallaria, 1 grain;
Powdered convallaria, 1 grain.
Make in one pill, and give a pill night and morning.

Or a syrup made of:

Extract of convallaria, 4 drachms;
Syrop of bitter orange, 6 drachms.
A teaspoonful night and morning.

In other cases we may use:

Tincture of squill, 75 minims;
Syrop of bitter orange, 1 ounce;
Distilled water, 3 ounces.
One teaspoonful every few hours.

Or,

Extract of squill, 1 grain;
Powdered squill, 1 grain.
Make into one pill, and give one night and morning.
Or,  
Theobromine, 7 grains.  
Place in one cachet, and give four a day.

Or,  
Caffeine, 15 grains;  
Benzoate of sodium, 30 grains;  
Syrup of bitter orange, 1 ounce;  
Water, 4 ounces.  
This may all be taken in twenty-four hours.

Or again,  
Powdered digitalis,  
Powdered squill,  
Powdered scammony, of each 1 grain.  
Make into one pill, and give one such night and morning.

Or,  
Carbonate of lithium, 7 grains;  
Lemonade with carbonated water, 1 pint.  
This is to be drunk each day.

Or, by the bowel:  
Nitrate of potassium, 30 grains;  
Oxymel of squill, 6 drachms;  
Milk, 3 ounces.  
This is to be given by the bowel.  
—La France Médicale, Feb. 24, 1899.

TREATMENT OF PALPITATION OF THE HEART.

LYON contributes to the Revue de Thérapeutique Médico-Chirurgical of February 1, 1899, a brief article on this subject. In the line of symptomatic treatment he orders absolute rest to quiet the circulation. External treatment may consist in the application of compresses wet with cold water to the precordia and spraying the skin of the chest over the heart with chloride of ethyl or ether. In other instances where an atomizer cannot be had, ether may be allowed to fall on the precordium drop by drop. Internally he prescribes the bromides in the dose of from fifty to sixty grains, thus:

Bromide of potassium,  
Bromide of sodium,  
Bromide of ammonium, of each 75 grains;  
Syrup of bitter orange, 8 ounces.

A dessertspoonful to a tablespoonful of this may be given once, twice, or thrice a day.

Or,  
Bromide of potassium, 75 grains;  
Tincture of valerian, 1 drachm;  
Syrup of peppermint, 1 ounce;  
Water, 3 ounces.  
A dessertspoonful to a tablespoonful a dose every few hours.

Or,  
Monobromated camphor, 7 to 10 grains.  
To be made into pills and all taken each day.

In regard to the treatment of a case in which the condition is one of erethism of the cardiovascular apparatus and hyperarterial tension, he not only prescribes rest, but orders an exclusive milk diet with the bromides and digitalis in small doses. Thus he gives

Bromide of potassium, 6 drachms;  
Tincture of digitalis, 30 minims;  
Distilled water, 10 ounces.

One or two tablespoonfuls may be given once or twice a day. In other cases strophanthus is of value; in others still, a pill composed as follows may be made:

Hydrobromate of quinine, 1 drachm;  
Powdered digitalis,  
Extract of convallaria, of each 30 grains.  
Make into 40 pills, and give one from two to four times a day.

In the palpitation due to arterial sclerosis he also believes that a milk diet is useful, and he prescribes iodide of potassium associated with the bromide, thus:

Bromide of potassium, 6 drachms;  
Iodide of potassium, 1 to 2 drachms;  
Distilled water, 10 ounces.

Two or three teaspoonfuls two or three times a day.

In other cases digitalis in small doses is prescribed as follows:

Tincture of digitalis,  
Tincture of squill,  
Tincture of aconite, of each 1 drachm.

Ten drops of this may be given twice or thrice a day for eight or ten days.

In the palpitation which is due to tuberculosis, improved hygienic surroundings, absolute rest, careful regulation of the diet, broiled meats, milk, and easily digested vegetables are necessary. Tonic wines, as that of cinchona or kola, are useful. Coffee and alcohol are also to be given if needed.

For palpitation of the heart depending upon chlorosis and anemia, ferruginous preparations are required, such as lactate of iron, citrate of iron, and hydrotherapeutic procedures such as cold douches and the wet sheet. This treatment is particularly necessary in cases where there is vascular atony or spasm, and in the spasm cases small doses of nitroglycerin are of value.

In reflex palpitation due to disorder of the stomach, careful regulation of the diet and the use of gentle laxatives should be resorted to, and should the palpitation occur in women, attention should be paid to the uterovarian apparatus, and metritis or prolapse should be carefully treated. Hydrotherapy is also useful in this class of cases.
When palpitation is due to toxic agents such as tobacco, coffee, or alcohol, the diet must be regulated, the most beneficial being the milk diet. The bromides may be given and hydrotherapeutic procedures resorted to.

In nervous palpitation, depending upon neurasthenia, the preparations of valerian are preferable to the bromides, and hydrotherapeutic procedures are very useful.

In palpitation associated with exophthalmic goitre he employs antipyrin, the bromides, and aconite, or should any evidence of dyspepsia be present he uses remedies for this condition.

THE TREATMENT OF EXOPHTHALMIC GOITRE BY SULPHATE OF QUININE.

Paulesco, in collaboration with Raynier, has made certain studies in regard to the pathogenesis of exophthalmic goitre. He believes that the principal trouble in this affection is the vasodilatation which affects the blood-vessels of the neck and head. As the result of this distention we have tremor, the goitrous swelling, and active congestion of the thyroid body which produces in its turn a hypersecretion of the gland, and which has a distinct physiological action. Paulesco claims that he has employed the sulphate of quinine with remarkable results, arising from its influence in producing vasoconstriction of the vessels of the head and neck. He gives fifteen grains of it at night after supper, and again a quarter of an hour later. He states that this treatment decreases the tachycardia, diminishes the exophthalmus and the size of the goitrous swelling.—Revue de Thérapeutique Médico-Chirurgical, Feb. 1, 1899.

THE USE OF THYROID GLAND IN THE TREATMENT OF RHEUMATIC AFFECTIONS AND ARTERIAL SCLEROSIS.

Lancereaux and Paulesco reported upon this subject to the Academy of Medicine of Paris at one of its recent meetings, and stated they believed that thyroid gland or its extract is useful in the treatment of chronic rheumatism and in the manifestations of arterial sclerosis, and also in vasomotor disturbances and in nutritional changes such as scleroderma.

In the case of a young woman who had suffered from a generalized scleroderma for two years, the results were most remarkable. The skin of the face was pigmented and had lost all its suppleness, so that the visage had become as immovable as a mask. The skin of the trunk and chest was pigmented and interfered with the movements of respiration, and there was also involvement of the skin and subcutaneous tissues in the upper extremities, so that there was difficulty of movement. Extract of thyroid gland given in the dose of seven grains a day, gradually increased in quantity as the patient bore it, produced rapid amelioration, the skin of the face becoming normal and that of the trunk more supple.

In a woman aged thirty-two years, with vasomotor disturbances in the extremities, similar treatment was instituted with advantage. When this patient was exposed to cold or suffered from emotion the extremities became exsanguinated and bloodless, and at times profuse sweating and salivation was present. Under treatment these symptoms entirely disappeared.

In a man of thirty-six years, suffering from chronic rheumatism with arterial sclerosis and high arterial tension with hypertrophy of the heart and sclerotic kidneys, thyroid gland given in progressively increasing doses did much good. The pains in the joints, the osteophytes, and the trophic troubles disappeared; at the same time the arterial tension was lowered, the polyuria and albuminuria decreased, the heart's action was quieted, and an arterial bruit disappeared.

Equally good results were obtained in a man of forty, who was suffering from general arterial sclerosis.—Revue de Thérapeutique Médico-Chirurgical, Feb. 1, 1899.

TREATMENT OF MOVABLE KIDNEY.

The Archives of Pediatrics for March, 1899, asserts that the treatment of movable kidney is not entirely surgical. In nearly every case some medical treatment is indicated, and in many cases no surgical treatment is required. When the affection, according to Comby, is latent or well borne, when the pains are moderate or intermittent in character, rest and an abdominal belt will suffice to relieve. Bandaging rarely succeeds on account of the great mobility of the displaced kidney. A flannel bandage wound several times round the body, and supporting the entire abdomen, is the best means of immobilization that can be devised. A bandage, however, tight enough to support the kidney is apt to cause colic or distress to the child.

It is of the highest importance that strain-
ing of the abdomen should be avoided; hence the bowels should be kept regular and free, dyspepsia should be promptly treated, and abdominal indigestion prevented if possible. Acute attacks of indigestion with vomiting should receive prompt treatment, for the act of vomiting is one of the most certain means of forcing a kidney from its normal position. It is practically impossible to keep a kidney in proper position after it has been once or twice displaced, if the child is subject to attacks of acute indigestion with vomiting.

The case should become a surgical one if the pains persist or become unbearable, or attacks of peritonitis or hydronephrosis through twisting of the ureter occur. An operation should then be performed for fixing the kidney to the posterior abdominal wall.

---

**FOR REMOVAL OF WARTS OF THE LID.**

Almon Brooks tells us in the *Ophthalmic Record* for April, 1899, that there is no remedy equal to fuming nitric acid, especially when applied on a toothpick or sharpened match, for the cure of warts on the lid. The growth is first denuded of its epithelial layer by means of a very sharp knife, when the sharp point of the stick carrying the acid is placed as nearly as possible in the center of the wart, and a boring motion imparted by rolling the stick between the thumb and forefinger. As soon as a smarting sensation is felt the application must be discontinued for the occasion. The process must be repeated (after three or four days), although two applications are usually sufficient when the papilloma is not large.

The advantages of this method are that it is painless, the absence of disfigurement during the treatment, the freedom from interruption of the usual occupation, and the recovery without a scar and usually without leaving a trace of the former site of the growth. It differs from the ordinary application of nitric acid in that the papilloma slowly shrinks and disappears, and is not merely burned away, as in the usual plan of dealing with such growths.

---

**THE PROGRESS OF THE SERUM TREATMENT OF TUBERCULOSIS.**

Dr. Davies, of Bristol, England, recently read a paper on the origin and development of bacteriology, in which he briefly traced the rise and progress of the germ theory of disease. He said that the science of bacteriology may be said to date from 1675, when Anthony van Leeuwenhoek, a linen-dyer, became interested in optics, learned the art of lens grinding, and managed to produce a lens with which he saw in rain-water living motile animalcules, smaller than anything seen before. In 1863 he presented a thesis to the Royal Society in London on a microorganism in tartar from between the teeth. Marcus Antonius Piancias, was the next investigator, and produced some valuable additions to the study of bacteriology; but it was not until Henle took up the question that the subject was appreciated at its full significance. Every year has added to our knowledge, and the advance made toward solving the mysteries involved in the origin of disease has within a comparatively short period been nothing less than phenomenal.

Quoting from Dr. Davies' paper, the leading points in the development of bacteriological technique have been as follows: In 1854 the use of the cotton-wool plug filter (Schröder and van Dusche); sterilization of culture fluids by heat; discontinuous sterilization (Pasteur and Koch); 1877, Weigert's introduction of the aniline dyes for staining bacteria; 1881, Koch's introduction of solid culture media—plate methods. Between 1849 and 1863 Pattender and Davaine worked on the anthrax bacillus. Then came Pasteur's work on pebrine or silkworm disease. In 1873 Obermeyer found the spirillum of relapsing fever. In 1880 Eberth and Koch observed independently the bacillus of typhoid, and in 1882 Koch published his discovery of the tubercle bacillus and Pasteur made his first communication on rabies. In 1884 Koch published his discovery of the cholera spirillum, and in the same year Loeffler described the diphtheria bacillus, and Nicolaier and Kitasato worked on the bacillus of tetanus. In 1892 the bacillus of influenza was discovered by Pfeiffer and Canon, and in 1894-96 Kitasato described the bacillus of plague then prevalent in Hong Kong. Although the origin of so many diseases has been shown to be bacterial, yet in the case of most of those in which an antitoxic serum has been also found and used, the treatment has hardly come up to the expectations formed of its efficacy. In no instance has failure been more conspicuous than in the serum treatment of tuberculosis. Koch by his discovery of the bacillus tuberculosis effected a complete change in the popular view regarding that disease, and when he later announced that he had also discovered its antitoxic, hopes
were raised that at last the scourge might be eradicated. Of course, the fact that these views were far too sanguine was soon made clear, and in the natural reaction of mind that followed a declining interest has been taken in the investigations of the workers who, undaunted by the first discouraging result, have ever since been plodding steadily on toward the desired goal. It cannot be asserted that their labors have as yet been attended by a large measure of success, or, indeed, that any definite advance has been made in the endeavor to produce a curative serum for tuberculosis. Nevertheless the fact that tuberculosis is not an actively infective disease should always be borne in mind, and that in consequence the difficulties in the way of finding thoroughly effective antitoxin are immensely increased.

The transference of immunity to tuberculosis was, as is pointed out by Dr. E. L. Trudeau and Dr. E. R. Baldwin, of the Saranac laboratory for the study of tuberculosis, successfully accomplished even earlier than the development of tetanus and diphtheria antitoxin. In 1888 Héricourt and Richet reported favorable results in transferring immunity to tuberculosis from dogs to rabbits by serum injections. Dr. Trudeau has been engaged in experiments on immunity to tuberculosis since 1891, and together with Dr. Baldwin since 1894, and the two have recently published a paper treating of their studies with serums during the latter period. The studies in question have been entirely confined to such experimental proof of the presence of curative and antitoxic properties in serums as could be obtained by laboratory methods, and the results of four years' work in experiments upon four sheep, three asses, twelve fowls, eighteen rabbits, and four hundred and fifty guinea-pigs is as follows:

1. A sheep was injected intravenously with killed thymus cultures. The result was so unsatisfactory that the serum tests were not conclusive.

2. Chickens were inoculated intraperitoneally with mammalian tuberculosis. The serum revealed no germicidal or inhibitory action on the tubercle bacilli, nor favorable influence on the course of the disease in guinea-pigs.

3. A sheep was injected with tuberculin. The serum was wanting in germicidal, antitoxic, or curative effect, so far as tested.

4. A sheep was inoculated intravenously with non-virulent cultures. Cachexia followed, and the serum was therefore not used.

5. An ass was inoculated as in 4; it died from pulmonary embolism. The serum was not bactericidal to tubercle bacilli.

6. An ass was inoculated with virulent tubercle bacilli and treated with tuberculin. The serum showed no germicidal nor curative but possibly some antitoxic effect.

7. An ass was inoculated with non-virulent tubercle bacilli and treated with various extracts of tubercle bacilli and dead bacilli. The serum showed no activity.

8. Rabbits were inoculated with non-virulent and virulent tubercle bacilli and recovered. Their serum possibly conferred some protection in tuberculin poisoning and possibly prolonged the lives of treated guinea-pigs.

The chief lesson learned from these experiments is that none of the serums appeared to prevent local or general reaction from small doses of tuberculin, nor to influence the temperature of tuberculous animals. The progress made in researches having for their object the discovery of an antitoxin for tuberculosis is slow and disappointing compared with the rapid strides toward perfection taken by the antitoxins for diphtheria and tetanus. Every day, however, fresh knowledge is being gathered in this particular branch of science, and the deeper the insight gained into the subject of immunity and antitoxins generally, the brighter will the outlook appear for the discovery of a tuberculosis antitoxin which will effectually cure the disease.—Medical Record, April 8, 1899.

ANTIPYRIN IN DYSENTERY.

Ardin-Deltat has employed antipyrin in the dose of seventy-five grains to eight ounces of water as a rectal injection in dysentery, given three times a day and retained for fifteen minutes. He claims that the relief from pain and tenesmus is immediate, that the number of stools is decreased, and that convalescence is speedily established.

STARCH DIGESTION IN THE STOMACH.

Austin states the result of a research on his part upon this subject in the Boston Medical and Surgical Journal of April 6, 1899. He says that from the results of his experiments the following facts seem to be well established:

Taka-diastase digests starch with remarkable rapidity in a neutral or slightly acid medium; and its rapidity is directly propor-
tional to the quantity of taka-diastase used. Taka-diastase in the above medium is capable of digesting three hundred times its own weight of starch in one hour.

The digestion of starch by taka-diastase is accelerated and enhanced by the presence of a small quantity of free hydrochloric acid, while beyond a certain amount the free hydrochloric acid retards and eventually arrests the diastatic digestion.

The digestion of starch by taka-diastase is not interfered with by organic acids for all practical purposes; on the contrary, the presence of a small quantity of organic acid enhances the diastatic digestion of starch.

The presence of albumin combined with hydrochloric acid seems to lessen the hindering action of free hydrochloric acid on starch digestion.

Albuminous foods—both of animal and vegetable origin—combine with, or neutralize, free hydrochloric acid of gastric juice, making the acid perfectly inert. The combined hydrochloric acid has no hindering action on diastatic digestion by starch.

In dogs' stomachs, when albuminous foods are given with starchy food, no free hydrochloric acid is found at the end of one hour, and in the meantime starchy foods are perfectly digested.

In the human stomach, when an ordinary regular meal is taken, the albuminous matter of the food combines with the hydrochloric acid of the gastric juice as fast as it is formed at least for a period of one hour, and such combined hydrochloric acid has no hindering action on starch digestion, and the diastatic digestion of starchy food is practically completed within that period.

SOME OBSERVATIONS UPON ERYsipelas AND ITS TREATMENT.

Charles M. Allen writes on this subject in the Medical News of April 8, 1899. He states that in treating and observing a group of one hundred cases he has been struck with the frequency of coexisting or preceding nasal affections in the facial cases. In former times these were almost always put down as "idiopathic," in contradistinction to the traumatic forms, or those in which some solution of continuity of tissue could be discovered. He says it has become his conviction that in the absence of cutaneous lesion or throat affection to account for it, the nose is the part through which ingress is effected by the cocci. In every instance of facial erysipelas observed (and the great majority have been of this variety) he has inspected the nares and made inquiry regarding nasal disease. The result has been that at least two-thirds of the patients gave evidence or history of disease.

Believing as firmly as he does in the efficacy of ichthyol, Allen has naturally turned to this remedy as well in combating the process at its seat of origin, and has applied in all cases a fifty-per-cent watery solution of ichthyol, so as to bathe the whole anterior and posterior nares as far as possible, covering over all fissures and excoriations at or near the introitus. Upon the skin surface he employed a twenty-five-per cent solution in colloidion. The results have been surprisingly good, and he has repeatedly been able to demonstrate to his assistants and to students a complete cessation of the process, so far as symptoms, temperature, and objective signs go, within twenty-four hours of the first visit. Many other patients were discharged cured upon the second or third day. Almost all the cases were seen early—i.e., in from twelve to twenty hours of the chill or earliest evidence of local inflammation.

Aside from an occasional prescription of ichthyol in pill form to correct some gastrointestinal disturbance, or something to relieve headache, no internal medication whatever has been made use of during the attack. During several years he has not given a single dose of tincture of iron in erysipelas. The adhesive band has been applied in a number of instances, usually in erysipelas of an extremity, in combination with the ichthyol paint, and always with the most gratifying results.

There have been no deaths to record in these one hundred cases, so far as Dr. Allen has been able to follow them, or to learn from the district visiting physician who might have seen some of the patients subsequently, although extremes of age are represented. In view of the fact that many subjects gave a history of one or more previous attacks, and the well known tendency of facial erysipelas to recurrence, he would strongly recommend attention to the nose and throat as a prophylactic measure, and has no doubt ichthyol will be found a useful drug in ozenas and chronic conditions requiring antiseptic and deoxidizing or reducing agents. The advantage of rubber adhesive plaster bands over the application of several layers of contractile collodion is that the latter is apt to break at some point,
and it is through this open door that the
erysipelatous process is seen to advance into
new territory just as water rushes through a
break in a dam and overflows the plain.

Dr. Allen recently treated a number of
children for erysipes of the extremities,
and has had most prompt results from what
he calls his "combined method." He now
has about fifty cases in which the adhesive
constriction has been combined with collo-
dion painting. He feels confident that if
this plan be resorted to early and be prop-
erly carried out, no necessity will arise for
scarification to produce a barrier, nor for
resort being had to antistreptococcic serum,
which so far as he can learn is of doubtful
efficacy in severe cases in infancy and child-
hood.

**BLACKWATER FEVER.**

*The Lancet* of April 1, 1899, contains an
article by Crosse on this important subject.
After discussing the pathology of blackwater
fever, and showing what he holds to be its
connection with malaria, Dr. Crosse comes to
the practical question of its treatment. In
dealing with this it will be well to bear in
mind that three distinct factors are present.
There is, in the first place, the attack of
malaria during which the hemoglobinuric
paroxysm develops; secondly, there is the
chronic malarial toxemia which has predis-
posed the patient to the attack; thirdly,
there is the sudden loss of hemoglobin,
which in its effect in no way differs from an
ordinary severe hemorrhage. The above
are present in all cases. Sometimes there is
another factor present in the subsequent
nephritis. It is clear that only the first of
these—namely, the malaria—would yield to
quinine. So far as is at present known,
quinine has only a parasiticide and not an
antitoxic function in malaria, and hence it
cannot be relied upon for treatment of toxem-
ia, and obviously not for the hemorrhage.
Quinine, therefore, should be given in black-
water fever, but with the express object of
clearing the blood of malarial parasites, and
hence it should be given in full doses similar
to those given in ordinary attacks of tropical
malaria. It must, however, be clearly un-
derstood that by the time a patient has
reached the point of hemoglobinuria his
tissues are probably much degenerated and
his vital functions seriously lowered; hence,
though we may cure his malaria by quinine,
we must not be surprised should he succumb.

A cachectic patient may be unable to with-
stand a severe hemorrhage; when to this is
added the constant and distressing vomiting
which often involves starvation, he is clearly
liable to die from exhaustion, as many of the
patients certainly do. On the other hand,
this is a very different thing from saying
that quinine is of no use in blackwater fever.
Dr. Crosse holds that it should be always
administered in doses sufficient to make it
certain that the blood is freed from parasites,
just as the first step in the treatment of a
patient suffering from sapremia due to re-
tained placenta is to clear out the uterus and
so remove any danger of further infection.

It is frequently difficult to efficiently ad-
minister quinine by the mouth on account of
the persistent vomiting, and administration
by the rectum is unsatisfactory. The author
is himself a strong advocate of the hypoder-
mic administration of quinine under these
circumstances, and in this practice says he
is supported by the profession in Italy and in
America—though, as far as he knows, many
English medical men hesitate to adopt it.
The advantage of the hypodermic method is
sufficiently obvious, for one can rest assured
that the dose which we administer is actually
absorbed. The supposed difficulties are really
hardly worth our consideration if we are thor-
oughly aseptic. Sulphate of quinine is not
suitable for hypodermic injection. Perhaps
the best salt is the hydrochlorate, which is
chiefly used in Italy; it is soluble in its own
weight of water. The acid hydrobromate,
which is soluble 1 in 6 of water, may also be
used, especially if the patient is liable to
cinchonism. Personally, when in Africa, Dr.
Crosse used the lactate, which is soluble (ac-
according to Squire, seventeenth edition, 189g)
1 in 6 of water. He is inclined to think that
ten grains of quinine administered hypoder-
mically every eight hours on the first and
second day would be a sufficient dose; after
this, he suggests that five grains should be
given twice a day till the end of the attack.
He also mentions that he always boils the solu-
tion of quinine and injects it while it is quite
warm. When the drug cannot be adminis-
tered hypodermically larger amounts may be
necessary. In a case of blackwater fever
which he recently saw in England, quinine
was at first given by the mouth; the patient
had a relapse. It was then given hypoder-
mically, and the patient recovered without
any further relapse. It is of course to be
remembered that quinine will accumulate if
the urine is either greatly reduced or sup-
pressed, and therefore it must not be contin-
ued in the same doses should this contingency occur.

So much for the treatment of the malarial element; as regards the other two factors the main indications are to maintain free excretion with the view to liberating the body from the accumulated toxins and to procure rest and nutrition, which will enable recovery from the anemia to take place. If the bowels are not opened a chologogue purgative and enema should be given; but overpurigation should be avoided. Dr. Crosse always administers sodium bicarbonate freely; this helps to allay vomiting and gastric pain, makes the patient more comfortable, does good by its diuretic action, and also helps to diminish the acidity of the urine. Opium should be given without hesitation to procure rest. Nutrition must be maintained by rectal feeding if necessary. Strychnine and digitalis may be necessary in cases of extreme asthenia; they will act beneficially by helping to maintain the renal blood-pressure and therefore the secretion of urine, for doubtless some of the cases of anuria occurring in blackwater fever are the result of collapse and not of nephritis. If nephritis occurs the usual remedies are to be adopted, but caution should be used in the administration of such depressing drugs as pilocarpine, from the use of which he has seen disastrous results; if it is decided to administer this drug, not more than one-sixth of a grain should be given at one time. After recovery the patient ought to be advised to take a holiday, if possible in England, and should not return at any rate until he has completely recovered from his anemia and cachexia. Indeed, on general principles it is probably desirable that no one should return to Africa after an attack. This is particularly the case where the blackwater fever has developed in spite of precautions, but applies less to those cases where the attack can be traced to exceptional hardship and privations which are not likely to be repeated. Those who, from one cause or another, cannot stand quinine, and those who suffer from even slight albuminuria, should not be selected for malarious climates. Finally, Dr. Crosse urges that prophylaxis of blackwater fever by habitual use of quinine will be found to be more hopeful than its treatment. He has come to the definite conclusion that besides adopting precautions in regard to exposure to chills, wet, and to the sun, and as to moderation in food, alcohol, and sexual matters, every resident in the more malarious parts of Africa should take at least five grains of quinine each day. In the large majority of cases Dr. Crosse believes that this would prevent the chronic malarial poisoning which is the predisposing cause of blackwater fever, and would do much to eliminate this scourge from the colonies.

**THE COMPLICATIONS OF THE SERUM TREATMENT OF DIPHTHERIA.**

This important theme is well discussed by Bolton, of Homerton, in *The Lancet* of April 1, 1899. He thinks that the value of the serum treatment of diphtheria being now thoroughly established, its complications, which are fairly constant, become somewhat important. During the past few months Dr. Bolton has collected at the Homerton Fever Hospital one hundred cases which he has personally examined each day, and on these cases his paper is based. These complications are the following: rashes, pains in and around the joints, fever, transient albuminuria, abscess, bruising, and sloughing at the seat of injection, and certain constitutional disturbances.

Bronchopneumonia, nephritis, and other inflammations, and also sudden death following the injection of antitoxin serum, have been recorded, but nothing of this kind has occurred in the London hospitals, where several thousand injections are given annually. The blood-serum is responsible for causing the rashes, the pains, and the fever, as these occur whether the horse from which the serum is taken be immunized or not. Different horses produce different effects with regard to the prevalence of pains and the proportion of the varieties of rash, and hence the percentage of these varies constantly. The effect of dose on the frequency of the rashes is very little if anything. Dr. Bolton has calculated out the average dose of all the patients treated at the Homerton Fever Hospital from January to June, 1898, neglecting those who died before the rash had time to appear, and finds that of those who developed a rash it was 6225.5 units, and of those who had no rash it was 5332.1 units. During the same period 166 patients had multiple injections, and of these 90 had a rash and 76 had no rash; and 351 patients had each one injection, and only 156 had a rash and 195 had no rash. Hence it is probable that large and also multiple doses increase the frequency of the rashes to a slight extent. Adults are more liable to severe pains than children. The severity of the
attack of diphtheria and the day of the disease on which the antitoxin is administered have no influence on the frequency of rashes and pains. For the year 1898 the percentages at the Homerton Fever Hospital were: rashes, 43.2 per cent; pains, 7.4 per cent; fever alone, 3.6 per cent; and abscess, 1.3 per cent.

There are two varieties of rashes, urticarial and erythematous, and these may occur alone or be combined in endless variety. Of the 100 cases, 25 were urticarial, 31 were erythematous, and 44 were combined; and of the latter 26 were mixed and 18 were successive, the rash following one another immediately or after an interval of from one to five days, either urticaria or erythema coming first. There may be more than two rashes of the same or different variety following one another. The time of appearance of these rashes varies from the second to the eighteenth day after injection, exceptional cases occurring at earlier or later periods, but the vast majority occurring from the seventh to the ninth day after injection. The dose does not affect the severity or time of appearance of the rash; doses of 4000 units, 8000 units, 12,000 units, 20,000 units, and 24,000 units may all cause a rash on the eighth day; 4000 units may cause it on the second day, or 8000 units on the eighteenth day. Multiple doses given at intervals of a day do not affect the time of the appearance of the rash, but if a patient has had antitoxin administered a month or two previously the rash which is caused by a subsequent injection comes out very early, in some cases from twenty to thirty minutes after the injection. The rashes last for two or three days as a rule; they often last for a week, and sometimes for sixteen days.

The wheals occur in groups and vary in size from a papule to a patch of half the size of an adult hand. They disappear quickly and leave patches of simple erythema, and are replaced by fresh ones. A wheal may come and go in half an hour, and successive crops may come out at intervals of from one to four days. Itching is present, and there may be urticaria factitia. The distribution is usually general. The favorite places on the trunk are the seat of injection, the shoulders, and the buttocks. Both the flexor and the extensor surfaces of the limbs are involved, but the latter more frequently than the former, and patches tend to collect round the joints. The neck, the cheeks, and the eyelids are commonly affected. The rash frequently begins at the seat of the injection and may remain limited to this area, and in few cases the limbs alone are affected. Edema of the cellular tissues often accompanies the urticarial eruption. The eyelids, the base of the nose, the cheeks, the lips, the scrotum, the prepuce, the labia majora, and the dorsa of the feet and the hands are the parts commonly affected; sometimes the whole of a limb is swollen, or in rare cases the whole of the body. The edema lasts from one to four days and may be accompanied by enlargement of the lymphatic glands.

Of the erythematous rashes there are four types: (1) resembling erythema multiforme, either clearing up in the form of rings or not, and sometimes becoming hemorrhagic; (2) simple erythema in patches; (3) scarlatiniform, resembling scarlet fever; and (4) morbilliform, resembling measles.

The first variety consists of macule, which may or may not be raised, and which vary in size from that of a papule to about that of a shilling. Large patches are formed by fusion, which may involve the entire circumference of a limb, or the macule may be chiefly discrete, and on the trunk especially they tend to be small, frequently giving rise to a very coarsely punctate appearance. The fusion into patches is especially marked on the extensor surfaces of the joints, and sometimes the skin desquamates in this situation and gives rise to the appearance of psoriasis. The macule are bright red or almost purple in color, and are sharply defined, the intervening skin being normal. Occasionally a few tiny vesicles may be seen on their surface. If the macule and patches clear up in the form of rings the latter may join together, forming gyrate figures, or they may be small and more or less discrete. On the trunk and opposite the joints huge rings may be formed, and on the trunk a large ring may sometimes be seen having its periphery formed of tiny macules more or less fused, with free macules dotted round its circumference, and the center fawn-colored and slightly desquamating. In a few cases the rash becomes hemorrhagic and a mottled pigmentation is left for a few days. There may be a little desquamation, and sometimes there is itching. The distribution of the rash is more definite than in the urticarial variety. On the limbs it is much more common on the extensor than on the flexor surfaces, and it is also more profuse on the extensor aspect, especially round the joints, where large patches or rings are very fre-
quent, with small macules extending up and down the limb. The rash occurs over the front and back of the trunk, forming large patches at the seat of injection (in the loin) and on the buttocks. It may be present on any part of the face and sometimes behind the ears. It may commence on the limbs, but very frequently at the seat of injection, and its distribution is usually general, although it may be limited to the limbs or the seat or seats of injection.

The simple erythema consists of non-raised, ill-defined, bright-red patches of irregular shape producing a blotchy appearance. It is most frequently the result of wheals, but it undoubtedly may occur independent of them. It occurs commonly at the seat of injection, where it sometimes extends from the loin on the back and the abdomen as a punctate erythema. It forms patches on the cheeks and on any part of the trunk and limbs. These erythematous patches are very fugitive, and it is often very difficult to say whether they are or are not the result of wheals. In some instances, as on the buttocks, they are due to pressure. There is no desquamation.

The scarlatiniform rash occurs very early and when the patient has had a previous injection some time before. In one case the patient had had antitoxin administered five months previously, and the rash came out on the day following the injection of 4000 units. This rash lasted for one day, and was replaced by an urticarial eruption lasting for four days; a macular rash then appeared for two days, and finally a crop of wheals for one day. The rash is a scarlet punctate erythema, thickest round the seat of injection, where it forms a bright-red flush. It is often thicker on the extensor than on the flexor surfaces of the limbs, and frequently clear patches of skin are visible. It may occur in patches only, chiefly on the trunk, and it is then combined with other rashes. When general it may be distinguished from scarlet fever by the usual absence of vomiting, the rapid disappearance of the rash, and the occasional patches of clear skin. It may also be accompanied by other rashes. Desquamation does not usually occur, and the rise of temperature may be slight.

The morbilliform rash is more frequent than the scarlatiniform, and is commonly preceded by an urticarial eruption, but it may occur alone. This rash is a macular erythema like measles, but it may begin on any part of the body and especially on the limbs, where it is more profuse than on the trunk and face. It is thickest on the extensor surfaces of the limbs, forming patches round the joints, and may be seen behind the ears. Patches of clear skin may be seen, and there may be ring-formation during the disappearance of the rash, which as a rule leaves no desquamation. There is conjunctivitis and frequently swelling of the lids, but sneezing and cough are as a rule absent. The rash lasts from three to four days, and there are commonly pains in the limbs. Fever may be absent, but as a rule the temperature suddenly runs up to about 103° F. when the rash appears, and falls either just before or when it disappears. Six out of the one hundred cases were of this variety. Four appeared on the fourteenth day after injection (the incubation period of measles being on the average about ten days), and had doses respectively of 4, 12, 16, and 24,000 units. The remaining two appeared on the twelfth and fifteenth day, and each had a dose of 12,000 units. Five were preceded by an urticarial eruption, and one by urticaria and macular erythema combined at the seat of injection. It is interesting to note that the scarlatiniform rash comes out much earlier than the morbilliform variety, and that the incubation period of scarlet fever is from two to four days, as compared with that of measles, which is ten days. By attention to the above points these two important rashes can generally be diagnosed from scarlet fever and measles respectively.

The joints and surrounding tendinous and muscular structures are affected, and there may be a little swelling of the joint, but it is quite the exception to find much fluid in the joint, and the skin over it is usually normal. In some cases the pains and temperature simulate acute rheumatism. The pains shoot about and shift from joint to joint, and there is also constant aching and intense pain on movement. There may be headache and furred tongue, and sodium salicylate produces relief. This condition lasts for three or four days, and in one case it lasted nine days. In other cases there may be simply a little aching in one or two of the joints which lasts for a day or two. When the pains have gone stiffness on moving the limbs is complained of. The joints most commonly affected are the knees, the remaining joints of the limbs being affected about equally. The hips, the knees, the wrists, and the hands are more commonly affected alone than any other joints. The
vertebral column is also frequently affected, and stiffness and pain in the neck and back are complained of. There is commonly pain in the temporomaxillary joint on opening the mouth, and less frequently in the sternoclavicular articulation. There is sometimes pain down the inner side of the thighs, in the popliteal space, and in the muscles of the calf. The pains occur with all forms of rash, and the temperature in these cases is usually coincident with the pain, except in the morbilliform cases, when the temperature is coincident with the rash. There may be a thick rash and shooting pains without any rise of temperature at all. The rash is frequently more profuse around the affected joints, and it may begin in the limb which is first affected by pain. The rash usually appears first, and the pain may occur at any time during the course of the rash, or exceptionally after it has disappeared. Less frequently the pain may begin and the rash appear in a day or two. The rash may start at the seat of injection, and when the limbs are attacked the pains appear.

A rise of temperature occurs most frequently with rash and pain, next rash alone, and rarely with pain alone. On referring to old notes of cases, rises of temperature are found at periods corresponding to those of the appearance of the rashes without anything to be noted to account for them, but personally Dr. Bolton says he has not observed a case of fever alone without either enlarged glands, otitis media, or some other cause. Fever occurs about equally with all forms of rash, and when associated with both rash and pain is almost always coincident with the pain, except in the morbilliform cases. When associated with rash alone it generally appears with the rash and may last throughout or disappear in a day or two. The rash may appear first, and sometimes the temperature only rises during the latter half of the period of the rash. In some cases the rise of temperature may precede the appearance of the rash. The course of the temperature curve is irregular, and its height may be anything between 100° and 105°, being especially high when associated with pain or in the morbilliform cases. Of the 100 cases, 26 had fever associated with rash and pain, 17 had fever with rash alone, 46 had rash alone, and 11 had rash associated with pain.

Of the 100 cases, 54 had albumin in the urine, and in 25 of these it was present before the rash appeared. This leaves 29 cases in which there was albuminuria during the course of the rash. In 24 of these cases there was a trace of albumin only, and it lasted from one to three days, and in two cases for six days, disappearing before the rash had gone. In the remaining five cases the albumin was present in considerable quantity, and outlasted the rash in three cases, disappearing with it in two cases. Neglecting these five cases, there remain twenty-four cases in which a trace of albumin appeared in the urine after the rash had come out and disappeared before the rash. Eleven of these cases had more or less fever at the time; hence there are left thirteen cases out of the one hundred with nothing to account for the albuminuria except that it was coincident with the rash. It may be argued that this albuminuria was a result of the disease itself, but on referring to the report for 1896 of the Metropolitan Asylums Board, it is found that the percentage of albuminuria for that year when antitoxin was used was 53.4 as compared with 24.1 in the year 1894, when no antitoxin was used. During the year 1896 every case of albuminuria, however slight, was included; but in 1894 at some of the Board's hospitals these slight cases were neglected, hence the percentage 24.1 is probably not high enough. However, under any circumstances there must have been a considerable difference in the two percentages, and this evidence is taken in favor of the fact that the thirteen cases mentioned above were the result of the serum. The amount of albumin was so slight, and it lasted for so short a time, that no possible harm could have resulted to the kidneys.

Abscess at the seat of the injection is no doubt due to infection through the needle, and is usually found in septic cases and in those complicated with scarlet fever. It is recognized in a few days as a tender, deep, localized swelling, the skin over it being normal. It readily heals up on being incised.

Bruising occurred round the seat of injection eight times in the one hundred cases. It may be at first of the size of a shilling and increase very little, or it may spread to the size of the palm of the hand. It appears in from one to four days after the injection, and lasts from four to seven days. In three cases the bruising was surrounded by a zone of small macules; in one of these the erythema came out with the bruise on the day after injection and disappeared on the following day, leaving the bruise. In the other two cases the bruising came out on the third day.
after injection and the erythema two days subsequently; the latter became hemorrhagic, lasting for seven days.

Dr. Bolton says as far as he is aware there is only one case of sloughing on record. The patient was one year and ten months old, certified as diphtheria, 6000 units of antitoxin being injected. On the next day the case was found to be scarlet fever. Eighteen days afterward the patient developed laryngeal diphtheria, and 8000 units was injected into the left loin. Half an hour after this latter injection there was a general eruption of wheals, and on the following day a bruise appeared at the seat of injection, which was surrounded by a red flush. Bullae then formed upon the affected skin, which subsequently sloughed over a considerable area, the underlying muscles being exposed. The child, who was seriously ill with scarlet fever and diphtheria, died at the end of fifteen days.

Three cases suffered from constitutional disturbance occurring soon after the injection, and they have been published in the appendix to the report of the Antitoxin Committee of the Clinical Society of London. In each case the patient had had previous injections, and each recovered. They all occurred during the year 1897, at the Homerton Fever Hospital, and were male children aged respectively four, six, and three years. The first patient (thirty-five days previously) had 12,000 units injected in three doses. Twenty minutes after an injection of 4000 units the patient had a rigor and convulsions with a temperature of 105° F. When this passed off the child vomited several times, and on the following day there was a mixed urticarial and erythematous rash. The second patient had 4000 units thirty-seven days previously, and thirty minutes after the injection of 4000 units had a rigor and became quite collapsed, with a temperature of 105°. On the following day a mixed erythema and urticaria appeared at the seat of injection. The third patient had been given 14,000 units forty-seven days previously, and fifteen minutes after 4000 units had been injected the patient vomited and was covered with a general urticarial eruption. Two hours later she had a rigor with collapse, and six days later still a macular erythema appeared.

In conclusion, one may say that the complications of antitoxin are at times very painful and inconvenient, but quite harmless, the only exception being the case in which sloughing occurred, and in that case the child was in an exceedingly bad condition as the result of scarlet fever and diphtheria combined when the antitoxin was administered.

CEREBELLAR ABSCESS.

Green (American Journal of the Medical Sciences, April, 1899) reports in very complete detail four cases of cerebellar abscess, and concludes that otitic abscesses of the cerebellum are due to extension of the inflammation either through the inner wall of the mastoid or through the labyrinthine passages. In the former the abscess is in the posterior portion of the cerebellum; in the latter in the anterior portion. The posterior abscesses can be reached by removing the inner wall of the mastoid, and then, by rongeurs or gouge and mallet, carrying the opening backward to any desired extent, thus exposing the cerebellum below and behind the lateral (sigmoid) sinus, thus giving most thorough and efficient drainage.

The anterior abscesses, such as those reported in the paper, offer much greater difficulties. They lie so far forward that to reach them from an opening behind the sinus involves puncturing the brain for from an inch to an inch and a half, and drainage for this distance nearly on a level must be inefficient. To reach them from an opening in the occipital bone below the superior curved line requires a greater length of puncture and gives even less favorable conditions for drainage. From a point just in front of the sinus, however, the distance to the orifice of the aqueductus vestibuli is only about one-fourth of an inch, and to the meatus internus about three-fourths of an inch. The posterior surface of the petrous bone can be removed for some distance forward and inward from this point, however, thus reducing these distances one-half. This method has the advantage of allowing the surgeon to explore outside of the dura along the posterior surface of the petrous bone, which cannot be done in most cases from an opening behind the sinus on account of the great projection of the vein. It has the disadvantage that the opening can never be very large, about half an inch in diameter being its greatest size. The removal of the posterior surface of the petrous, where the bone is very thick, solid, and lying deep, is much facilitated by the use of gouges slightly curved on their hollowed sides for half an inch at the ends.

Whether these anterior cerebellar abscesses
will prove to be as amenable to treatment as the posterior ones experience has yet to show. The cases cited show the difficulties of reaching the lesion, even after it has been located, for in all three the labyrinth was the path of infection.

FURTHER CONSIDERATIONS OF THE MECHANISM OF EAR VERTIGO AND ITS RELIEF BY REMOVAL OF THE INCUS.

BURNETT (American Journal of the Medical Sciences, April, 1899) appends to his article with the above title a case of parotitic ear vertigo cured after a year's duration by removal of the incus.

The paroxysmal nature of ear vertigo can be explained only by assuming that it is due to temporary increase in retraction and impaction of the stapes in the oval window or temporary engorgement of the labyrinth from within, without compensatory yielding of the stapes, and a consequent pressure on the labyrinth water and the ampullae. That such is the mechanism of ear vertigo is demonstrated by the curative effect of removal of the incus and liberation of the stapes. Why true ear vertigo occurs paroxysmally cannot be explained, but Burnett suggests that it is due to varying degrees of tension in the chain of ossicles or in the labyrinth fluid. The latter, being a part of the lymph system of the subarachnoid space (Hasse), must be subject to varying conditions of tension, as are the ventricles of the brain or the cerebrospinal fluid. Ordinarily the compensatory yielding of the fenestrae of the labyrinth toward the drum cavity is sufficient to prevent undue pressure in the ampullae and vertigo. If, however, these yielding points are stiffened as in chronic middle-ear catarrh, in which there is always more or less retraction and impaction of the stapes and thickening of the membrane of the round window, then either an increased quantity of endolymph or perilymph, or both, emanating from the cranial cavity, or a spasmodic or further retraction of the chain of ossicles and impaction of the stapes from tympanic causes, as occurs in chronic aural catarrh, is competent to excite a paroxysm of ear vertigo.

If the liability to these paroxysmal impactions of the stapes can be prevented and greater freedom given to the movement of the stapes outward when its foot-plate is pressed upon from within, ear vertigo from the causes mentioned can be prevented. Such immunities can be granted by removal of the incus and consequent liberation of the stapes. In twenty-seven cases of ear vertigo in which Burnett thus liberated the stapes, entire freedom from incapacitating attacks of ear vertigo followed the operation. This relief did not always come at once, as long a time as six months having elapsed in some instances before entire relief was obtained; but in some of the worst cases immediate relief followed the removal of the incus, as in the case reported. In a few cases the tinnitus was entirely relieved, and in the rest of the cases greatly relieved, by the operation. The hearing, uniformly very defective in true ear vertigo, was uninfluenced by this operation.

TREATMENT OF TETANUS BY INTRACEREBRAL INJECTION OF ANTITETANIC SERUM.

QUÉNU (Journal des Praticiens, No. 11, 1899) reports five cases of tetanus, two of which occurred in his own practice, the remainder in the practice of Beurnier, Veslin, and Lariau. These were all treated by intracerebral injections of antitetanic serum, and all died.

TREATMENT OF ABSCESS OF THE BRAIN.

COLLINS (American Journal of the Medical Sciences, April, 1899) terminates a clinical summary of the treatment of abscess of the brain by the statement that a brief retrospect of the more important literature on brain abscess for the past year shows a deplorable mortality. The most potent factor in contributing to this frightful mortality is the failure to recognize the existence of abscess of the brain before it has produced either septic complications or profound exhaustion. Surgical technique has apparently very little, if anything, to do with it. The mortality-rate of brain abscess will drop just in proportion to the earliness of recognition and the courage of the physician in directing the surgeon to seek for it, even though there be no exact localizing symptoms. Abscess of the brain secondary to middle-ear disease is located in the vast majority of cases either in the temporal lobe or in the cerebellar hemisphere of the same side. When one is reasonably sure of the existence of brain abscess, no hesitation should be had in exploring first one of these regions, and then, if it is not found, the other. Delaying the operation until the appearance of unequivocal localizing symptoms, or procrastinating by operating
on the mastoid after symptoms of brain abscess are evident, when one is reasonably assured that abscess exists, is a far greater injustice to the patient than subjecting him to an exploratory trephining.

**THE SURGICAL TREATMENT OF PERFORATING AND BLEEDING WOUNDS OF THE CHEST.**

**Matas** (Journal of the American Medical Association, April 1, 1899) in his paper upon this subject recognizes that there will ever be a certain percentage of penetrating chest wounds which will inevitably end in death, just as there will be others that will recover without treatment, with the simplest mode of treatment, and even in spite of treatment. But there is an intermediate zone, occupied by those in whom it is evident from the first that they have not sustained an immediately mortal injury; it is this doubtful zone which will furnish the battle-ground in which it will be possible for timely and skilful intervention, with the new aids here described, to tip the balance so that some will live who would otherwise die.

The dangerous hemorrhages of the chest that more frequently give the surgeon an opportunity for the application of direct hemostasis are those resulting from pteryal, pulmonary, and diaphragmatic wounds. Hemorrhages from the aorta and its large intrathoracic branches, the heart, the pulmonary arteries and veins before they penetrate the hilum, the vena cavae and vena azygos, are promptly fatal, especially if due to gunshot wounds; indeed, these are the chief causes of the great mortality from chest wounds on the battle-field. The fact that bleeding from the internal mammary or intercostal vessels is frequently covered up was clearly impressed upon the mind of the author by two cases of stab wounds of the internal mammary artery and one of the intercostals that came under his own observation. In at least one of these cases a careful and thorough examination would probably have averted a fatal end.

In conditions of great exhaustion, and where there is doubt that bleeding is actually going on, it may be sufficient to plug the wound with a bag, which is then so thoroughly packed with gauze that by making traction upon its neck the wounded vessel is firmly compressed from within outward; but when the situation does not improve, and there is evidence that bleeding is going on, the quickest and surest treatment is to enlarge the wound, using cocaine anesthesia as a help in extreme exhaustion, and to expose the intercostal or internal mammary. A subperiosteal resection of the rib is usually certain to expose the bleeding vessel, and is so easily accomplished that there is no excuse for delay in critical conditions when the patient's life hangs in the balance.

As to what shall be done in case the hemorrhage is from the lung, and not from the parietes, it can be stated that as yet there is no commonly accepted order of procedure. Superficial, wounds of the lung give rise to insignificant hemorrhage, and the parenchyma bleeds but little. Nélaton has shown by experimental research that wounds of the large vessels at the root of the lung, before they subdivide in the substance of the organ, are invariably fatal in from nine to ten minutes. What are the wounds, then, that give rise to the hemorrhages which, though very serious, would allow of sufficient survival to permit of surgical interference? According to Nélaton's investigations they are the arterial branches of the second and third magnitude which accompany the larger divisions of the bronchial tubes. Therefore, the most dangerous zone of hemorrhage is a comparatively circumscribed area in the neighborhood of the hilum; the zone rapidly diminishes in importance as the bronchi become smaller and lose their cartilaginous resistance. Once the conviction comes that the patient is bleeding to death, prompt and decisive action is called for, without losing time in abstract possibilities of spontaneous recovery. Hence the secret of success lies in the judgment of the practitioner who knows when to act, and not wait until the opportunity has passed.

Before undertaking a formidable operation, however, the patient's capacity of resistance to shock or further traumatism must be carefully weighed, and due preparation must be made for the serious contingencies that will certainly arise in the course of the operation. Fatal shock, uncontrollable hemorrhage, cardiac and respiratory failure, are dangerous incidents to surgical intervention. Matas believes that this intervention should be preceded by an intravenous hot saline infusion, as a means of preventing shock. Moreover, preparations for artificial respiration, either Fell-O'Dwyer's or other apparatus (a bellows with a tube inserted in the larynx), should be made. A cannula is first inserted into the vein, so that salt solution can be injected the moment it is required. An osteoplastic flap
can often be formed by using Schleich’s solution. Before sectioning a rib upon the proximal side, the intercostal nerve must be thoroughly anesthetized. If, under the influence of the saline infusion, the pulse fails to improve, it is perfectly useless to continue with the operation, and all hope of operative relief must be abandoned, unless the cardiac failure is attributable to respiratory embarrassment from collapse of the lung, when inflation of the lung by means of the bellows should be tried in conjunction with the saline infusion. The customary hypodermic and stimulant treatment is always applicable in these cases.

It is interesting to note that Matas considers that saline infusion is an agent to be relied upon when all other remedies in the materia medica fail. He states that it is not only vivifying, but almost resurrecting.

As to the precise method of operating little need be said. The opening into the chest wall must be very free, or the bleeding vessel will never be found. If made in the lateral aspect of the thorax, it should suffice to expose the entire external surface of the lung, and the internal also, if the organ is lifted up and dragged out of the chest.

THE TREATMENT OF TABETIC ARTHROPATHIES.

Ullmann (Centralblatt f. Chirurgie, No. 6, 1899), as the result of an extensive study of the literature of the subject, and of his own experience, has collected the following cases of resection: One at the shoulder-joint, with prompt healing; two of the hip, with thoroughly satisfactory results; five of the ankle, with three excellent results; nine of the knee, with one good result, four failures, and two deaths.

Thirteen amputations are recorded—eight primary, five secondary. Three primary amputations of the thigh were followed by two failures; in the third the result is not known. Out of five amputations of the leg, three were cured. The results of the five secondary amputations were unfavorable.

It is interesting to note that there were quite as many cures following resection as amputation. This, perhaps, is explained on the ground that secondary amputations were usually performed at a period when the patient was much exhausted by a persisting suppuration. It is only when the spinal disease is little advanced, and the patient is able to be up and about, that a resection should be performed. Under other circumstances, when the patient’s life is threatened by suppuration, amputation is indicated. To avoid recurrence after resection, orthopedic appliances must be employed.

THROMBOSIS AND EMBOLISM OF THE MESENTERIC VESSELS.

Firth (Bristol Medico-Chirurgical Journal, March, 1899) sums up as follows the knowledge of mesenteric thrombosis and embolism to be gained from modern literature:

The usual result of occlusion of the mesenteric vessels is infarction of the intestine. This infarction may follow occlusion of either the arteries or veins, the effect generally being greater when the latter are obstructed, for in that event there is no hindrance to the supply of blood by the artery, but there is hindrance to the escape, and of necessity there is produced intense vascular engorgement and often extravasation of blood in the affected area. When the superior or inferior mesenteric artery is blocked, engorgement also follows, the flow of blood producing it in this case being from the anastomosing arteries and from the veins, the backward pressure of the latter coming into play when the vis a tergo is cut off. Litten’s experimental ligation of the superior mesenteric artery near its origin, in dogs, always produced this result.

Though infarction of the intestine and mesentery, with gangrene in the severest and ulceration or simple congestion in the mildest cases, most frequently follows occlusion of the superior mesenteric artery, yet in two cases observed by Virchow and one by Tiedemann the artery was found obliterated without injury to the intestine. Chiene has also reported a case met with in the dissecting-room, in which there was occlusion of the three anterior branches of the abdominal aorta supplying the viscera. The vitality of the intestine had in no way been impaired, having been maintained by the dilatation of collateral blood-vessels. It appears from these cases that the intestine escapes injury from interference with normal channels of blood-supply if the interference is sufficiently gradually produced to allow of compensatory dilatation of anastomosing arteries.

Councilman remarks upon the probability that small emboli frequently enter the superior mesenteric artery, their entry being favored by the size of that artery and the angle it forms with the aorta; but that the
free anastomosis between its small branches prevents these small emboli impairing intestinal nutrition. He reports three cases of embolism of the superior artery which he had met with. One of these is particularly interesting, for clinically the symptoms were those of complete intestinal obstruction, with vomiting finally becoming stercoraceous, great abdominal pain, and tympanites. The patient, who was eighty-five years of age, died on the twelfth day of illness. The intestine presented a few small ecchymoses, but there was neither intense congestion nor at any place complete infarction. A thrombus attached to an atheromatous patch on the anterior wall of the aorta, just above the origin of the superior mesenteric artery, almost completely occluded the opening of that branch. He thinks it probable that the blood-supply through the obstructed vessel, though sufficient to maintain the vitality of the intestine, interfered with its innervation, leading to paralysis of the bowel and the attendant intestinal obstruction. In a second case, though the entire superior mesenteric artery was obstructed, there was only a beginning of infarction in a small area of the intestine.

Dr. Elliot has analyzed the records of twenty carefully reported cases of occlusion of the superior mesenteric artery, in which the abdominal symptoms were not overshadowed by those of heart disease or by coma. All the cases were rapidly fatal. Pain, often colicky, was the most prominent symptom, and occurred in nearly all. A very notable symptom was the presence of blood in the stools. This was recorded in thirteen cases. In three the blood was passed without feces. In six the hemorrhage was profuse. In three other cases neither feces nor flatus was passed. Hematemesis occurred in three. Blood is usually found in the intestines at the autopsy, even if not passed during life, and is also frequently found in the peritoneal cavity. In two cases there was a palpable swelling, which proved to be infarcted bowel; and in another a swelling was due to a collection of blood in the mesentery. Subnormal temperature and extreme pallor were noticed in several cases, due no doubt to hemorrhage and peritoneal shock. In nearly half the cases there was diarrhea. In some there was neither diarrhea nor other disturbance of the bowels. The source of the embolism is usually vegetations on the cardiac valves, or on atheromatous patches in the aorta.

Watson, analyzing eight cases of total occlusion of the main trunk of the superior mesenteric artery, finds that in one case there was entire absence of abdominal symptoms, and in two others they were very slight, though the infarction affected a large part of the intestines. On the other hand, in a case in which only a small portion of the intestine was in a state of infarct, abdominal pain was sudden and violent, and there was profuse bloody diarrhea. It is obvious, therefore, that from the clinical signs it is impossible to tell the extent or degree of the intestinal lesion.

It will have been noticed that one of the most characteristic symptoms mentioned above was bloody diarrhea. If there is evidence in other parts of the body producing, for example, gangrene of the feet, or hemiplegia, hemoptysis, and chest pain, or splenic or renal trouble, the diagnosis of the condition under discussion will be much facilitated; but this evidence is often wanting. Again, the presence of heart disease and atheromatous arteries will help in the diagnosis. Watson thinks it possible to diagnose about one-fourth of the cases.

The affection, perhaps, most closely resembles intussusception, as pointed out by Elliot. In both infarction of the intestine and intussusception there is often diarrhea and intestinal hemorrhage, and pain and vomiting. The hemorrhage is apt to be more profuse in the embolic affection, but has been recorded as the principal cause of death in both. In intussusception tympanites is rare in the early stages. In that affection, too, the patients are usually younger. According to Fitz, fifty-six per cent of the cases of intussusception are under the age of ten. The characteristics of a tumor if present would be an important guide to the diagnosis.

A few cases are recorded of embolism of the inferior mesenteric artery, but the symptoms do not sufficiently differ from those in which the superior artery is affected to permit of clinical differentiation. It has been said that the presence of fresh blood in the dejections, and the localization of the pain in the lower part of the abdomen, point to embolism of the inferior vessel.

Elliot has found fourteen reported cases of thrombosis of the superior mesenteric vein. They were even more rapidly fatal than those of embolism of the artery, nearly all having died on the second or third day with symptoms of intestinal obstruction. The symptoms of this affection are much the
same as those of embolism of the corresponding artery, with the exception that diarrhea has not been recorded as present in any of the cases. Blood was vomited or passed in large quantity by the bowel in half the cases. In five of the cases there was cirrhosis of the liver, and two were syphilitic. In two cases a volvulus was considered to be the result of the thrombosis.

It may, therefore, be said that acute abdominal symptoms, associated with the passage of blood and with portal obstruction from cirrhosis of the liver or other cause, would suggest the diagnosis of thrombosis of the mesenteric veins.

The prognosis in these affections of the mesenteric vessels is very bad, though, as mentioned above, there are records which show that patients have survived. Elliot has only found in literature three cases which have been operated upon. He reports two additional cases of his own. In none was the diagnosis previously made; and four out of the five died unrelieved.

Laparotomy, and resection of the intestine if it be found to require it, is the only treatment that offers any prospect of success. Watson states that the records of a number of autopsies showed that one-sixth of the cases might have been relieved by such treatment. In the single successful operation for this condition on record, that of Elliot, four feet of intestine, almost gangrenous from infarction, was removed. The open ends of the intestine were sutured to the abdominal wound, and the artificial anus thus produced was subsequently closed by a second operation. The patient was a male, aged twenty-five, and the cause of the infarction was thrombosis of the mesenteric veins. Elliot’s second case was one of thrombosis of a branch of the mesenteric artery. An artificial anus was made in the descending colon; but the patient died. At the autopsy four inches of the intestine was found gangrenous and perforated. In most cases the presence of heart disease, atheroma, or cirrhosis of the liver militates strongly against surgical success.

Once in a ten-year-old boy, suffering from gonorrheal cystitis, which had lasted for several years without yielding to other forms of treatment, urotropin was given for about seven weeks, in doses of about three grains five times daily.

A girl, two and a half years old, had suffered from cystitis for eight months. She was cured in three months by giving her, five times a day, one and a half grains of urotropin. This treatment was continued for three months.

In one child, aged seven, the medicament seemed futile. Operation showed pyelitis (hydronephrotic), because of a congenital stenosis of the ureter.

The drug should be kept up for some time after apparent cure and without intermission. It seems to be of little service when the urine is acid. The daily dose varies between eight and thirty grains.

**ENTEROPLASTIC OPERATION TO OVERCOME OR PREVENT STENOSIS, WITH ESPECIAL REFERENCE TO THE SPUR IN PRETERNATURAL ANUS.**

Fenner (American Journal of the Medical Sciences, April, 1899) states that the principle of overcoming a stenosis of a canal by transverse union of a longitudinal incision is applicable in any portion of the intestinal tract below the duodenum wherever the mechanical conditions will permit.

The longitudinal incision or opening should be made in the middle of the convex surface—that is, equidistant from the two sides of the mesentery, so as not to interrupt blood-supply by the division of large vessels in the intestinal wall. Free mobility of the loops of intestine and intact peritoneal covering are desirable conditions, but the latter is not absolutely necessary. In places where the intestine has no mesentery and where there is a limit to the infolding or bringing into apposition of the convex surface or the surface of the intestine opposite the mesentery, as the cæcum, extraperitoneal border of the rectum, or flexures of the colon, there is a limit to the length of the longitudinal incision. It is evident that the length of the longitudinal wound should not be unnecessarily great.

When there is no mesentery, and consequently only slight mobility, for folding in or apposition of the convex free surface of the intestine, or where the mobility is diminished or lost by diffuse inseparable adhesions, there

**CYSTITIS OF CHILDREN TREATED BY UROTROPIN.**

Heubner (quoted in Centralblatt f. die Gesamme Therapie, April, 1899) reports excellent results from the use of urotropin in cases of cystitis in children. In two instances this drug was followed by cure.
is, of course, a limitation to the application of this principle.

This plastic operation, when applied to resection and circular suture, will enable us to avoid narrowing of the intestine by folding in of its wall at the place of suture. If, for the sake of additional safety, it is deemed desirable to apply a second row of seromuscular sutures at a distance of one-half centimeter from the first row, the advantage of having a larger amount of serous surface in contact is counterbalanced by the increase in size of the circular fold. The narrowing effect of a large fold can be overcome entirely by the plastic operation, because we can make the longitudinal division long enough to secure a circumference of any size desired.

The same principle is applicable when we wish to unite an intestine of small caliber end to end with one of large caliber. By longitudinal division of the smaller intestinal tube the line of union is easily made to correspond to that of the larger tube. If the lumen of the larger intestine is not deemed sufficiently wide to permit of so much folding in as is required, a longitudinal division is also here resorted to, until at last as large a line of union as we deem desirable is secured.

In artificial anus, whether this be the result of a premeditated operation or of an accident, where the mucosa of the intestine is finally united to the skin, it is commonly observed that the so-called spur forms a more or less complete obstruction to fecal passage from the proximal into the distal portion of the intestine. The spur, so to speak, leads the bowel contents from the bowel out through the opening in the skin. The distal portion becomes small and retracted from non-use.

The spur is formed by a semicircular fold or group of folds located opposite to the opening through the abdominal wall at the place of the bend of the opened intestine. This semicircular fold may increase so as to extend entirely around the lumen of the intestine, thus becoming a circular fold, and is then located at the end of the proximal portion of the intestine close to the opening in the skin, through which it may protrude as a prolapse of the mucosa or wall of the proximal bowel. When this spur is well developed it may form, even when the intestine is loosened from the abdominal wall, an impediment to free fecal passage that frustrates simple transverse or longitudinal suture of the intestinal opening, and consequently necessitates resection of the loop containing the spur.

As resection with subsequent circular suture is as yet an operation of some gravity, it would be an advantage to avoid resection and still overcome the stenosis and the influence of the spur with a more simple operation.

A patient presented himself with a fistula in the right inguinal region which would admit the little finger. This fistula was circumcised about an inch and a half from its border, through the skin, subcutaneous tissue, and abdominal muscles, down to the transversalis fascia; this circular flap, like a collar, was loosened and closed tightly by a continuous silk suture, so that none of the intestinal contents could pass out. The abdomen was then disinfected, and clean covers were put on the table and the patient. The peritoneal cavity was opened one inch medial to and above the fistula. The isolation of the loop with the fistula was relatively easy. It was found to be a loop of small intestine. It was freed from adhesions, pulled up out of the wound, and surrounded by gauze. The loop of gut which it occupied was emptied of its fecal contents and ligated by means of gauze strips, two to three inches on each side of the fistula. The abdominal wall-flap was then cut off from the border of the fistula. It was evident that simple union of the fistulous opening either in the transverse or in the longitudinal direction would not do away with the stenosis caused by a ring-shaped valve of the mucosa, consequently could not remove the impediment to the passage of feces at this point. The effect of this spur was overcome by a plastic operation performed as follows:

1. A longitudinal incision at the convex border of the intestine one inch in length in the proximal end of the intestine through the tongue-shaped valve, up into the normal intestinal wall above it.

2. A longitudinal incision, one inch long, into the distal or narrower portion of the intestine below the spur, thus making a longitudinal wound two inches in length on the convex border of the intestine. As the original fistulous opening was two centimeters in diameter, the wound would be about three inches in total length. Upon making the incision at the upper end of the wound Fenger saw a Peyer's patch.

The spur formed a circular valve of two or three parallel folds of mucosa, half an inch broad, most pronounced on the mesenteric side, extending around the entire circumfer-
ence of the intestine, but smaller on the convex border.

3. Transverse union of this longitudinal wound: (a) Suture united the upper and lower corners and was left long for traction, dividing the wound into two transverse halves with the suture in the middle; (b) a continuous silk suture through all the layers of the intestine; (c) a continuous serosa-muscularis suture, one centimeter outside of the former; (d) a second continuous serosa-muscularis suture to bury the former.

4. Disinfection of the sutured loop with 1:1000 sublimate solution, and removal of the gauze ligatures around the loop of intestine.

5. Removal of the sponges and examination of the abdomen for hemorrhage.

6. Step sutures of the abdominal wall.

7. Gauze drain down to the appendix and over to the sutured loop of the ileum.

8. Injection of two quarts of physiological saline solution into the rectum.

The operation lasted three and a half hours. At its close the patient's pulse was good; no shock. The patient recovered.

---

BILATERAL MAMMARY CANCER.

Albert (Wien. Med. Woch., Jan. 7, 1899) has met with four cases of bilateral mammary cancer among several hundred cases of that disease. In two he operated. The first patient was thirty-seven; she underwent amputation of a cancerous left breast, not ulcerated, with clearing of the axilla. Both the tumor and the axillary glands proved carcinomatous on microscopic examination. As an open wound was left, epidermis was grafted, on Thiersch's principle, from the patient's left thigh. Five months after the operation a mass as big as a walnut was removed from the cicatrix, but it extended into the deepest layers of the soft parts of the thoracic walls. When the wound was healing a tumor developed in the right breast, and was removed six weeks after the second operation; the axilla was cleared. About three weeks later a deposit was detected below the left axilla. Operation was impossible, as it clearly extended into the thorax. The patient died with symptoms of pneumonia just ten months after the removal of the left breast.

The second patient was fifty. A small cancerous tumor developed in the outer upper quarter of the left breast; the skin adhered, yet the tumor had hardly been observed over a month. The breast was removed, the axilla cleared. One year and a half later a small cancer developed in the center of the right breast, and the gland was removed, the axilla being also cleared. The patient recovered quickly, but no after-history is given.

In two cases no operation was performed. The patient in one case was a very big woman; her breasts stood prominently forward, owing to infiltrating cancer; the skin was stretched, and bore lenticular malignant deposits. Otherwise the case resembled lymphosarcomatosis of the breast.

The last patient was thirty-six. She had allowed a cancer of the right breast to go on for two years, and for five months the left had been involved; the disease seemed most advanced in the gland last attacked; the whole breast formed a tough mass fixed to the pectoralis muscle. Cachexia had not set in.

Hansy (Wien. Med. Woch., Feb. 11, 1899) reports a case in a postman, aged sixty-one, adding two photographs. The patient applied at hospital for a large ulcerated cancer of the left nipple, which had existed about a year, with corresponding disease on the right side; the latter had grown with great rapidity, and ulcerated extensively. Disease was clearly advanced, the growths adhered to deeper structures, especially on the left side, and both axillae contained masses of hard but painless glands. On September 6, 1897, the right mamma and the axillary glands on both sides were removed; the ulcer representing the remains of the left gland was scraped out and cauterized. The patient returned to his duty as postman, but died on May 1, 1898, of cancerous marasmus, with symptoms of internal metastases.

---

CYST OF THE PANCREAS TREATED BY INCISION AND DRAINAGE THROUGH THE ANTERIOR ABDOMINAL WALL.

Pollard (British Medical Journal, March 11, 1899) has treated three cases of pancreatic cyst by drainage through an anterior abdominal wound. It has been objected to this method, on the one hand, that the adhesion which must of necessity be formed between the anterior and posterior walls of the abdomen might be injurious, and on the other hand, that possibly simple drainage might not effect a permanent cure of the disease. The author has delayed publication
of his cases in order that, in regard to them, time might show the validity or otherwise of these two objections. It is now nearly five years since the first case was operated upon; the second case was operated upon three years ago, and the third case two years ago.

The first case, thirty-four years old, was, in the early part of 1894, awakened one night by a sharp pain in his epigastrium, which caused vomiting. This persisted two days, when the vomiting ceased, and the severe pain was replaced by a burning sensation in the epigastrium, whence it radiated to the throat. The pain, associated with occasional attacks of vomiting, had persisted since. During the last six years the patient had suffered from some half-dozen similar, though less severe, attacks. His temperature ranged about 100°, and the upper part of the abdomen and the lower part of the chest on the left side were bulged, owing to the presence of a mass which could be felt to occupy the whole of the left hypochondriac region and a large portion of the epigastro-umbilical and left lumbar regions. This mass moved slightly on respiration.

The abdomen was opened by a six-inch incision in the left linea semilunaris. The cyst, which lay behind the stomach and transverse colon, was opened in the interval between the stomach and transverse colon. The great omentum was divided transversely, and the lesser peritoneal cavity was opened. A strip of gauze was packed into the wound between the stomach and the transverse colon, and the abdominal wound above and below this spot was closed. A dressing was then applied. On the sixth day the gauze plug was removed, and about three pints of fluid was withdrawn by means of a hydrocele trocar. Two days later an anesthetic was given, and after the removal of two pints of fluid by tapping the cyst was freely opened. The dense fibrous wall bled freely, therefore packing with cyanide gauze was practiced. On the following day this was removed, and a large drainage-tube was inserted. Six weeks later the man was still wearing a tube four inches long. This was continued for upwards of a year. The tube was then removed, and in less than a week the sinus closed permanently. Since the operation the patient has had occasional attacks of burning pain in the epigastrium—the last one nearly two years ago. The general health has been greatly improved. A hernia formed at the seat of abdominal incision.

The second case began by general malaise, which was followed in a few days by shortness of breath. During the night he was awakened by severe abdominal pain, which was followed by vomiting; these attacks recurred. In about two weeks a tumor was detected. Upon admission to the hospital a large mass could be felt occupying the left upper quadrant of the abdominal cavity; it did not fill the loin, nor cause bulging. On deep percussion there was slight resonance. When air was injected into the rectum a well-marked tympanic note was obtainable in the left flank and at the upper part of the abdomen. This resonant area was behind the tumor. A four-inch incision was made, a little to the left of the middle line, over the most prominent part of the tumor. The great omentum was torn through, the cyst wall was exposed and was punctured with a hollow needle, and after sufficient fluid had been withdrawn to render the cyst walls lax, an incision about one inch long was made into the cyst, and its contents, about three pints, was withdrawn. The abdominal wound was sutured at each end, and the margins of the incision into the cyst were secured by several stitches to the margins of the central portion of the abdominal wound. The tube was removed in about four weeks, and the patient recovered completely. A small ventral hernia formed at the seat of the abdominal incision.

The third patient, aged thirty-six, first began to suffer with pain in his back; this was followed by sudden pain in the left hypochondrium, which spread up into his chest and nearly choked him. He kept his bed for a month, during which time the severe pain subsided, but the pain in his back continued. The tumor was noticed about the time that he began to suffer from back pain. The tumor occupied the left loin, but did not fill nor bulge it. The growth moved a little with respiration and was also slightly movable from side to side. It felt distinctly elastic. The operation was the same as in the preceding case. In about eight weeks the resulting sinus was closed. A hernia formed at the site of the drainage.

In none of these cases was there a history of pancreatic injury. In all the onset was characterized by severe epigastric pain, and the urine was free from sugar. The stools appeared natural, and there was no excess of undigested fat. In each case the fluid removed at the operation contained the three digestive ferments of pancreatic juice, but after they had been drained for a few days the discharge from the cysts was found.
to have lost its digestive powers over starch and fibrin.

Pancreatic cysts have come forward in at least three different situations, namely, above the stomach, opposite the small omentum; between the stomach and the transverse colon, opposite the great omentum; and below the transverse colon, opposite the descending layer of the transverse mesocolon. The second of these positions is the most common.

The removal of the cysts has been recommended. The operation has been performed successfully in some cases, but in several there has been a fatal termination. Since it is now clear that drainage alone will suffice for the cure of these cysts, removal is no longer a justifiable operation. The advisability of draining these cysts through a posterior incision has been urged. If the lumbar operation could be performed safely without making an anterior incision, this would be the method to be preferred, but in many cases the anterior incision would be required to verify the diagnosis, and possibly to determine the exact spot at which the cyst could be best reached by the posterior incision. It must not be forgotten that important structures and large blood-vessels may be encountered in attempting to reach the cyst through an incision below the last rib, and that owing to want of space it might be difficult to recognize and avoid them. The only objection to anterior drainage which has become apparent is the occurrence of hernia at the spot where the presence of the tube prevented primary union in the abdominal wound.

OINTMENT FOR HEMORRHIOIDS.

Nehigan (Der Frauenartz, Feb. 20, 1899) prescribes the following ointment for hemorrhoids:

- Compound tincture of camphor, 1 drachm;
- Camphor, 1 drachm;
- Belladonna ointment, 15 drachms.

To be applied directly to the painful part.

TREATMENT OF FRACTURES BY MASSAGE AND MOVEMENT.

Milhiet (Journal des Praticiens, No. 11, 1899), following in this the teaching of Forgue and Reclus, and indeed the teaching of nearly all progressive and experienced surgeons, urges the necessity of recognizing not only in exceptional cases, but in nearly all instances of fractures, the powerful healing help which is offered by a wisely directed massage and movement. In fracture the solution of continuity is not the only lesion. There is always an effusion involving the surrounding soft parts. This effusion, if not quickly absorbed, becomes organized into plastic lymph, which may seriously cripple the functions of joints and tendons, and may contribute to atrophy and degeneration of the muscles, vessels, and nerves. Massage is the most powerful means we possess of causing rapid absorption of this effusion, and of preventing the atrophy and degeneration which often persists for many months after a fracture has become completely consolidated, and so maintains a disability which should not exist. Even when the skin is blistered or broken, and when veins are dilated, massage, if practiced in an aseptic manner, is applicable. It is only when aneurism is present, or when the fracture is dependent upon malignant infiltration, that this method of treatment is positively contraindicated.

As a lubricant, oil, borated or camphorated vaselin, potato starch, talc powder, or rice powder, may be used.

Massage should be practiced from the very beginning, always in the region of the fracture, usually directly over it. The rubbing should be in the direction of the venous circulation, and should begin with slight stroking. A preliminary application of compresses wrung out of hot water is often advisable, because of its soothing effect upon the pain, and its stimulating influence on the local circulation. After stroking for some time the pain is usually greatly lessened; then deeper motions may be practiced. Forgue and Reclus advise two rubbings a day, each of a quarter of an hour's duration at first; later the treatment may be lengthened. After having finished massage, the neighboring articulations should be carefully moved. Thus the troublesome stiffness which commonly follows fractures is avoided.

Certain fractures show no tendency towards displacement; for instance, a Colles' fracture which has been well reduced. Under such circumstances a fixation splint should be omitted entirely, and massage should be practiced as above described. When the fracture is attended with very slight mobility and displacement, a fixation splint is kept on for as little time as possible. When fractures are attended by great mobility and displacement, such as those of the femur and humerus, for instance, the immobilization is usually necessary for a time; this treatment should be made as brief as
possible, however, and should be supplemented by massage and movement of the joints nearest to the fracture.

THE TREATMENT OF SYPHILIS.

Taylor (New York Medical Journal, April 8, 1899) again enters his protest against the alluring routine treatment of syphilis, which has become all too popular in our system of medicine. He states that before considering the subject of treatment proper, it is very important to call attention to certain vicious therapeutic methods which still prevail to a certain extent, but which he thinks are slowly passing into desuetude.

About twenty years ago a most unfortunate reaction took place in the method of treating syphilis. Prior to that time it may be confessed that the method of using mercury was in general rather too lavish in its doses, and that in some cases harm was done. But the old-time Ricord plan of treatment (in vogue prior to 1870), in which an active mercurialization for six months, supplemented with three months' liberal dosage with the iodide of potassium, was, with all its drawbacks and imperfections (chiefly salivation and intestinal derangement), far more beneficial than the attenuated, emasculated, narrow-gauge, stencil-plate methods of treating syphilis which then were adopted in France, England, and America. The reaction from the vigorous use of mercury was too radical, and we complacently accepted a method of treatment built up on theories and fantastic reasoning, which has proved to be one of the most calamitous events in medical history. We hear little to-day in America of the ingenious and sophistical reasoning of the accomplished author of the interrupted treatment of syphilis, and there are few who wrestle with the labyrinthine problems of dose arithmetic, with its "full dose," "tonic dose," and "reserve dose," in administering mercury according to the tenets of the prepostorous tonic treatment. But although these ingenious theories are either entirely forgotten or unknown to the present generation, the trail of the serpent is still visible in the routine methods followed by many in blindly relying upon the stomach ingestion of insoluble preparations of mercury in small doses. Happily for the human race, this slip-shod, happy-go-lucky method of treatment is less and less followed every year.

Chemical examinations have shown (and any one can ascertain the facts for himself) that when mercury does not produce gastrointestinal derangement, a goodly amount of the drug is absorbed, as proven by its excretion in the urine and feces. When matters thus progress favorably the effect upon the syphilitic condition is beneficial, but as time goes on chemical examinations show that the quantity of mercury assimilated grows less and less, and that though taken by the mouth, it is not absorbed, and that its therapeutic effect is then lost.

Clinical observation has clearly shown that for a time, in the early weeks of syphilis, a decidedly beneficial effect is produced upon the disease by mercury given by the stomach, but that in a few weeks the therapeutic action begins to wane and soot the remedy becomes inert. It is this temporary action of mercury given by the stomach, in long-continued and interrupted courses, which has brought to thousands of patients great trouble and suffering, misery, disaster, and death. They took the remedy long after it ceased to have any therapeutic effect, and the unextinguished infection kept right on its course of invasion and destruction.

When shall active medication begin? The best results are always attained when treatment is commenced just as soon as the secondary manifestations show themselves.

The date (as a general rule) at which the treatment of syphilis should begin is that at which the disease culminates in the general infection of the economy—namely, just as soon as the general rash appears, together with the other manifold symptoms of the secondary period.

Too much stress certainly cannot be laid upon the fact that in the early secondary stage there are certain conditions favorable to an active treatment—namely, a system virgin to mercurials and a greater susceptibility of the lesions to the action of mercury. This, then, is the most favorable time for efficient treatment, and it is the most critical one in the life of the syphilitic, for if the disease is attacked then its backbone may be broken.

It is always well to begin medication in a manner that will not annoy, disgust, or discourage the patient, who is usually in a rather unhappy frame of mind at the thought that he is syphilitic and that he has quite a long period of treatment before him. Therefore, it is not well to be precipitate in the institution of an injection treatment. Since in these early days mercury by the mouth is generally well borne, is effective in result,
and is not distasteful to the patient, he may at once be put upon pills of the protoiodide of mercury, or of tannate of mercury, or of the thymol acetate of the same. In general, half-grain doses of these drugs may be given three times a day, and it will be rarely necessary to increase the daily amount taken beyond two or three grains of any of them.

It is important that this initial course should be active and rather prolonged, and in attaining this end the case must be carefully handled and watched. As a rule, the physician can form a correct estimate as to the probable effect of mercury upon his patient within a week or ten days. Having put the stomach and intestinal canal in normal condition, and the mouth and throat having received proper attention, the dose of the mercurial may be increased within a few days to the quantity which acts vigorously on the lesions and does not disturb the wellbeing of the patient.

We must at this time assure ourselves that the indurated nodule has wholly disappeared, that the lymphatic engorgement shows evident signs of involution, and that the rash has faded or is fading. The throat and mouth must be inspected very often, and any red patches or ulcerative lesions must be actively treated. It is always a good rule as the rash is declining to discontinue the pills and to give the patient one or two courses of mercurial inunctions, by which the whole surface of the body will be acted upon by mercury. In this way any infectious cells which may be left over from a local or general rash may be acted upon and destroyed. Even while the patient is taking pills mercurial ointment may be used locally upon the lymphatic ganglia, due care being taken that an overdose is not given. In like manner papular and pustular lesions in hairy parts should be treated locally.

By thus at an early date inducing the patient to use inunctions of mercurial ointment as an adjuvant treatment, it is seldom difficult, particularly with intelligent persons, to gain their consent to follow a full inunction treatment, and then the use of the pills may be discontinued. In proportion as the case progresses well the fear of the disease by the patient is dissipated and his morale improves. At this time the assurance on the part of the physician that the patient will be very much more benefited by systematic inunction treatment generally results in the patient's consent.

To be effective, the mercurial inunctions should be thoroughly administered over the whole body in regional parts, using about sixty grains of mercurial ointment. In some cases the inunctions may be administered on consecutive days; in others there may be intervals of one or two days between them. Usually after fifteen or twenty inunctions a period of repose may be allowed for a week or two, since after such a course fully three or four weeks elapse before mercury ceases to be eliminated in the urine and feces.

Either synchronously, or in the intervals of disuse of the mercurial frictions, we should give the iodide in goodly doses—ten, twenty, or thirty grains three times a day, or even in larger doses.

Then, again, it may be necessary, for various reasons, to suspend the inunction treatment for a long or short time, and in this event use a strong mixed treatment, as follows:

- Hyd. binod., gr. ij to iv;
- Potass. iodid., 3 as to 3 f;
- Tinct. cinch. co., 3 lif;
- Aqua, 3 f.
- M. j in die ex aqua 3 f.

In this way we can push along until six months have elapsed from the date of the onset of the secondary period of syphilis, during which time the patient has taken medicine more than five months. In most cases, if this carefully regulated and most effective treatment has been followed, an examination of the patient will show that he presents no evidence of the disease, and that his condition is most satisfactory. Then the patient may have a respite from medicine for two or three weeks. At the expiration of this time the treatment must be kept up for three months longer, and it must consist of alternations of the inunction treatment and the dosage with a mild or strong mixed treatment. As a cure progresses the intervals between inunctions may be longer, and the mixed-treatment dosage may be less strong.

After the lapse of a year, in many cases, the necessity for treatment may not be apparent, and most of these patients say that they think they are perfectly well. It is better, however, not to take any chances, and during the second year, and perhaps a little longer, a few courses of inunctions and of the mixed treatment may be taken.

In the carrying out of this methodical general treatment of syphilis in the second year of the disease, the periods of dosage may on an average be stated at two to three months, with intervals of rest of a month.
or six weeks. In this way about eight months is occupied by actual medication. In most cases at the end of the second year of thorough treatment patients may be pronounced cured, provided they have not for many months shown evidence of the disease, that their lymphatic system appears healthy, and that their general health and nutrition are good.

Bangs (New York Medical Journal, April 8, 1899) holds that if it is admitted by the majority of syphilographers that histologically all of the secondary manifestations of syphilis are found to be composed of the same cell accumulation, with perhaps the development of a few connective tissue fibers, as compose the initial lesion itself, why should it be argued that there is "nothing to treat until generalization has manifested itself?" Again, if specific treatment of the initial lesions be warranted in particular cases, why is it not warranted—and indeed required—in all cases?

If, then, an initial lesion is present, and if specific treatment is good for it, why not begin at once the administration of that remedy which we know hastens the involution of those manifestations which belong to the so-called generalized or secondary stage? The effects of syphilis are due not only to the mechanical interference with the function of the part or parts where these exudes take place, but also to a systemic poisoning due to the elaboration and circulation of a toxin or protamine produced by the micrubic body itself. If the vital forces of the individual are maintained at what might be termed a par of health, and all his functions kept at the highest point of activity, his economy is better able to take care of the toxins, while by the judicious administration of mercury his body is enabled to dispose of the granulomata or cell accumulations in their varying grades of intensity. This implies constant watchfulness, the exercise of careful, discriminating judgment, and in some cases ingenuity, on the part of the doctor, and on the part of the patient obedience, confidence, and patience.

As to methods of administration, if the remedy is well borne when taken by the mouth, this is the preferable mode. Only so much should be administered daily as can be digested easily and freely without interfering with stomach and intestinal digestion, but up to the point of the drug's physiological action. In the majority of cases a habituation to the remedy ensues, and therefore it is well to make intermissions in the treatment from time to time; always, however, maintaining the hygienic and dietetic status quo of the person. It should be observed that many persons do not bear the internal administration of mercury up to the point that may be necessary to act vigorously upon their lesions. In such cases the method of inunction should be resorted to at once. This is less depressing than the vaporization method, is not at all painful, and in spite of the staining of the skin is less disagreeable than the hypodermic method, and is often brilliant in its results.

It is a good custom during the course of the treatment of syphilis to intermit the internal administration of the drug, even if it is well borne by the stomach, and substitute inunctions, always keeping in view the general principles upon which the drug is administered.

In certain malignant forms, where the tissues of the individual seem to be rapidly breaking down as a result of the disease, hypodermic injections of the bichloride may be given with very prompt effect. They should be repeated with care, bearing in mind the fact that death has ensued from this method of using the drug. With ordinary precautions, however, and choosing the buttocks for the site of the injections, there is but little danger.

Even in cases of malignant syphilis the effect of the injections should be watched very closely, and every possible accessory measure taken to increase the general well-being of the patient.

One of the most important guides to indicate the period during which treatment should be carried on is the condition of the glands throughout the body, particularly the epitrochlear and those which are not usually found enlarged in the more common dyscrasias. So long as these glands remain enlarged, it is one indication at least that treatment should not be discontinued. Enlargement of the glands alone is not positive evidence of syphilis, but if the practitioner has followed his patient from the onset of the disease, and has appreciated that these enlargements have grown smaller or disappeared entirely under treatment, it is confirmatory evidence that they are syphilitic in nature. If the individual gives a suspicious history and has glandular enlargements, it is well to give him the benefit of the doubt and administer mercury; but at the end of three months, say, if no material change has taken
place in the size of the glands, it may be reasonably concluded that connective tissue changes have occurred in them to such a degree that they are now permanently enlarged.

The duration of the treatment, irrespective of the state of the glandular system, will depend somewhat upon the individual and the continued activity of his disease. But experience teaches that long-continued and gentle treatment for at least three years (some authorities say five, and one has lately urged seven) affords the patient protection from the effects of the disease later in life.

NERVE TRANSPLANTATION.

Petersen (American Journal of the Medical Sciences, April, 1899), from a study of twenty reported cases of nerve transplantation, finds that the median nerve alone was operated upon in seven cases, the ulnar alone in three cases, and the median and ulnar together in two cases. The musculospiral was operated upon in seven cases, and the sciatic in one case.

The injuries to the nerves necessitating transplantation in ten cases were due to removal of tumors involving the nerves; incised wounds were responsible for four cases; injury following operation for necrosis twice; while gunshot wound, operation for gluteal abscess, ununited fracture, and simple fracture were responsible for one case each.

There were eight primary and twelve secondary operations. The time elapsing from date of injury to time of operation varied from forty-eight hours to one and one-quarter years. Eight out of the twelve cases of secondary operation, or two-thirds, showed improvement in sensation or motion, while only four out of the eight cases of primary operation, or one-half, showed signs of improvement. However, two of the eight cases were observed only ten and six days respectively.

The distance separating the central and peripheral fragments varied from three to ten centimeters. As far as can be judged, the distance did not seem to affect ultimate results. In nine cases the transplanted segments were from sciatics of dogs, in five from recently amputated limbs, in three from the sciatics of rabbits, and one each from the spinal cord of a rabbit and the sciatic of a kitten. In one case the excised nerve was itself implanted.

In nine cases catgut was used to unite transplanted segments to central and peripheral ends of excised nerves, in three silk, and once kangaroo tendon was employed. In seven cases no mention is made of the suture material.

Strictly speaking, no case can be said to have recovered entirely, if by that be meant a complete restoration of sensation, together with a return of the muscles to their former size and power. The nearest approach to this condition occurs in the case longest under observation, where at the end of six years sensation had entirely returned, and the only remaining weak muscle was the adductor of the thumb. In three cases there was practical recovery of sensation and motion, so that the hand was entirely useful. In two of these both median and ulnar nerves were operated upon.

There was complete return of sensation recorded in four cases. In three cases there was nearly complete return of sensation. Improvement in sensation was recorded in four cases, while improvement in muscular power is noted also in four cases.

There was improvement in either muscular power or sensation in twelve cases, while in six cases there was no improvement in either sensation or motion.

The shortest time any case was under observation was six days; the longest six years. Of the five cases under observation one year or more, three made nearly complete recoveries in both sensation and motion.

The average time in which sensation first appeared after the operation was about ten days, while the average time for the first appearance of motion was about two and a half months.

The general conclusions deduced from this study are as follows:

1. Transplantation of a peripheral nerve segment to bridge over a gap between the two ends of a resected nerve is a legitimate surgical procedure.

2. Under favorable conditions at least partial and at times complete restoration of sensation and motion may be expected to follow the operation.

3. Regeneration of the degenerated peripheral end is due to down-growths from the axis-cylinders of the central end.

4. From the slowness of this process the longer the time after operation the more favorable will be the results.

5. Sensation may return very early after operation, and as a rule precedes return of motion.
6. This rapid return of sensation is not due to down-growth of axis-cylinders or to conductivity of the transplanted fragment, but must be explained by collateral nerve supply.

7. In many cases very early return of motion after transplantation may be due to vicarious movements of other muscles than those formerly paralyzed, and not to a regeneration of the latter's nerve supply.

Reviews.

This volume, which we have gone over pretty carefully, is perhaps the most interesting of the series. It deals with the subjects of Croupous Pneumonia, Cerebrospinal Meningitis, Dysentery, Yaws, Inflammation, Erysipelas, Simple Continued Fever, Relapsing Fever, and Typhoid fever.

In the opening article upon Croupous Pneumonia, by Dr. Andrew H. Smith, of New York, we are told that it is "an acute disease in which a specific parasite invades the air cells of one or more pulmonary lobes, where it grows in the fibrinous medium exuded from the functional capillaries and generates a toxin which infects the system at large."

Surely this definition does not admit the fact, which we believe is generally recognized, that the microorganism of pneumonia is capable of infecting the entire system, and we are somewhat in doubt as to what is meant by the term "functional capillaries." In that portion of the article which deals with the treatment of pneumonia, Dr. Smith states that as a heart stimulant in cases of circulatory failure with relaxed blood-vessels, strychnine takes the foremost rank, and he believes that the remedy may be pushed to the point of producing muscular twitching. We have already asserted our belief a number of times in the editorial columns of the THERAPEUTIC GAZETTE that the continuous use of strychnine in large doses is disadvantageous, and that it is to be used rather as a whip in cases of sudden collapse than as a constant stimulant, since it simply acts by nervous irritation. In connection with the use of digitalis, we regret to find that Dr. Smith is not very favorable to its employment—indeed, he speaks very strongly against its use, unless at the same time an arterial dilator is employed. This we regret, not because we do not believe that in many instances nitroglycerin should be combined with digitalis, but because it seems to us to be a sweeping decision against a drug which undoubtedly can be used in many cases with very good results. What Dr. Smith says of digitalis will have a tendency to prevent physicians from employing it in any case, when they should employ it in some and not in others.

In quoting Dr. Mays' statistics concerning the value of cold in the treatment of pneumonia, Dr. Smith evidently ignores the fact, also ignored by Dr. Mays, that in these statistics there is no differentiation between lobular pneumonia and lobar pneumonia, and therefore they cannot be considered as having great bearing upon the point at issue. In his résumé of the treatment of this disease, Dr. Smith tells us that the treatment should consist in an attack upon the pneumococcus through the medium of the blood with the object of causing the exudate when it escapes into the air-cells to be impregnated with the substances which will unfit it to serve as a culture medium. We confess that we have not found anything in medical literature or in practice up to the present time which in the slightest degree carries out this much to be desired effect.

In Dr. Sodré's article upon Dysentery, we are told that of all drugs recommended in the treatment of this disease that which has given the best and surest result is undoubtedly ipecacuanha. While the majority of the profession some years ago were in accord with Dr. Smith in this belief, we are inclined to believe that in the majority of cases of dysentery this method of treatment is not now commonly employed, having been supplanted chiefly by the aromatic sulphuric acid and magnesium sulphate treatment.

We regret that Dr. Kiliani in his article upon Erysipelas does not mention the use of ichthychol locally in the treatment of this disease. Surely, of all the local applications which have been employed, this is the most efficacious. Neither do we find any mention in this article of the employment of tincture of the chloride of iron, which certainly is receiving professional indorsement. Indeed, the whole question of the internal treatment of this disease is decidedly ignored.

In the article on Simple Continued Fever we find that amongst the synonyms are given sun-fever, gastric fever, catarrhal fever, mountain fever, and abortive fever, all of which
goes to illustrate the fact that the term "simple continued fever" is in many instances a cloak to our ignorance of the real condition which is present. We think that the majority of medical leaders at the present time consider that gastric fever, at least as it occurs in children, is in a great majority of cases due either to acute catarrh of the stomach or to typhoid infection; indeed, gastric fever is a term which is commonly employed to indicate a type of typhoid fever in which the gastric symptoms are particularly marked. So, too, abortive fever is a term which is sometimes employed to indicate cases of typhoid which run an unusually short course. Sun-fever is probably due to disorder of the nervous heat mechanism by exposure to the sun's rays, and it has been definitely proved that mountain fever is a true typhoid infection slightly modified by the physical surroundings of the patient.

The article on Typhoid Fever is written in two parts: the first by Dr. Thacher, who deals with the etiology and general pathology of the disease, and the second by Dr. Brannan, who deals with the symptomatology and treatment.

We are sorry that Dr. Brannan recommends meat broths, as we believe that all animal broths when given to typhoid fever patients afford excellent culture media for the development of the bacillus of Eberth, and also for the numerous other pathological micro-organisms which are found in malignant activity in the alimentary canal during the course of this disease; for truly typhoid fever is associated with multiple infection. Neither do we think the description which is given as to the manner in which the cold pack is to be used is correct. Surely the patient who is first wrapped in a cold sheet and then wrapped in a large blanket is speedily placed in a hot moist pack, owing to the fact that the blanket retains the heat of his body, and evaporation, the most important factor in reducing temperature, is prevented.

Dr. Brannan, in mentioning Dr. Woodbridge's treatment of typhoid fever by the administration of antiseptic and purgative substances, quotes certain passages in Dr. Woodbridge's writings which it seems to us are antagonistic to general professional opinion, as, for example, that death is a really unnecessary consequence of typhoid fever, and that every case in which the above treatment is instituted sufficiently early in the course of the disease can be aborted. This is certainly a very dangerous statement and does not agree with our knowledge of the natural history of the disease; and while Dr. Brannan does not quote it with his indorsement, we notice that he is in favor of the so-called eliminative and purgative treatment. The statistics which he gives, however, in regard to the Woodbridge, Thistle, and other methods in typhoid fever, are truly inadequate to determine the value of any method of treatment. Those who have had a large experience with this disease know full well that it is by no means an uncommon occurrence for several hundred cases to pass through typhoid fever and for the mortality to be exceedingly low, and then the next hundred cases will have a very high mortality, the variation depending largely upon the susceptibility of the patient and the virulence of the infection. Thus Mason has recorded five different series, aggregating 242 cases, with five deaths, or a mortality of about two per cent; but the total mortality of 676 cases was 10.4 per cent. We are sorry that Dr. Brannan has emphasized this method of treatment, and has not emphasized other methods which we think are more valuable. We also regret that practically nothing is said about the use of alcohol in the treatment of cardiac weakness. While it is mentioned as a drug which may be used, no sufficient directions are given as to its employment.

It has been well said that in the reviewing of a good book or the criticism of a work of art, it is the custom to point out only the faults and none of the good points. It may seem to our readers that this custom has been carried out in reviewing the present volume. We have mentioned the points in which we disagree with the various authors; we now wish to add what we have already intimated at the beginning of this review, namely, that this volume is an exceedingly valuable addition to the series, that the articles are unusually good, and that, taking them all in all, they well represent modern medical thought.

There are few writers in purely scientific medicine who are skilful enough to present the facts before them in so interesting and practical a manner as to be rewarded by a call for five editions within eight years of the appearance of the first, yet Dr. Abbott has embodied so much useful information in his text that this creditable fact holds true in
regard to his little volume, which is a small octavo of about 600 pages, including the index. The earlier chapters deal with the consideration of the first studies which were made of microorganisms, and then with the description of various parasites of a microscopic character. Passing on from this subject he deals with the principles of sterilization, with the principles involved in the methods of isolating bacteria, with those of the properties of nutrient media and the technique of bacteriological investigation, with a description of the various forms of apparatus which are needed for the study of these important organisms. The first part of the work concludes with a chapter upon inoculation of animals and their post-mortem examination. The second deals with the methods which should be employed to obtain material, with the processes of suppuration, septicemia, tuberculosis, diphtheria, typhoid fever, and with organisms which are capable of infecting man and the lower animals, as for example the bacillus of anthrax and tetanus. The concluding chapters deal with infection, with a bacteriological study of water, air, and soil, and the methods of testing disinfectants and antiseptics. An appendix describing the apparatus necessary for beginners in the bacteriological laboratory closes the volume.

To the ordinary practitioner who has not the opportunity to do bacteriological work, the second part of the volume will prove most interesting and useful, particularly the chapters dealing with infection and the methods of testing disinfectants, antiseptics, etc. The type in this book is unusually good, and this, combined with the easy style of the writer, makes it a delightful one to read, as well as of increasing one’s information in regard to this ever-increasing subject.

Dr. Heitzmann tells us that in adding another to the long list of works on the examination of the urine, he has been guided by the fact that microscopic examination, and especially microscopic diagnosis, have not received as much attention in text-books as their importance calls for, while chemical analysis has been thoroughly treated in a large number of works. For this reason he naturally devotes himself chiefly to the study of the microscopic examination of the urine, but begins his volume with an introductory, which is followed by chapters upon the chemical examination of the urine, in which he deals with its general physical and chemical properties, and its normal and abnormal substances. In the second part he takes up the microscopic examination, and considers the various forms of apparatus which are employed and the character of the bodies which are seen in the urine by the aid of the microscope. The first part takes up only 33 pages, but the second part, or that dealing with the microscopic examination, takes up 113 pages; while the third part, which is entitled “Microscopical Urinary Diagnosis,” deals with the lesions which are found in the various forms of renal and genito-urinary diseases. This part extends over nearly 100 pages.

We do not see in looking over this book that it differs materially from a number of other volumes upon the same subject that we have reviewed in the last year, except that it is more thorough and wider in its scope, not only dealing with substances which are ordinarily found in the urine, but with extraneous substances such as wool-fiber, starch globules, lycopodium granules, and various forms of vegetable matter. The book is a first-rate one, but does not seem to have any distinct originality, a characteristic which it would be almost impossible for it to present.

As we have pointed out in reviewing earlier editions of this well known book, it is one which will prove much more useful to the student of pharmacy than to the student of medicine, and that it does meet a distinct need in pharmaceutical literature is evidenced by the fact of its being in the seventh edition. The book is a small octavo of about 400 pages, and deals with the origin, habitat, description, allied plants, constituents, and properties of the various drugs which are official. The portions of the text devoted to the consideration of the properties of the various drugs are exceedingly condensed, too much so to permit of the information being used in therapeutics. On the other hand, it is a most excellent summary of materia medica from a botanical point of view, and in those schools of medi-
cine in which the somewhat old-fashioned method of teaching materia medica by studying the botany of medicinal plants is still carried out, the book will doubtless continue to be popular, as it is undoubtedly the best one of this class. From what we have already said, it is evident that it fully meets the needs of pharmacy students.

**Annual and Analytical Cyclopaedia of Practical Medicine.** By Charles E. de M. Sajous, M.D., and 100 Associate Editors and Corresponding Editors. Illustrated with Chromolithographs and Maps. Volume III.

It is but a few months since the second volume of this interesting and complete work edited by Dr. Sajous appeared. The criticism which we made in the earlier issues of the Therapeutic Gazette concerning the predecessors of Volume III holds true also in regard to this one, namely, that the volumes attempt to deal with medical literature scattered over too large a number of years. On the other hand, this very wide scope enables the various contributors to give quite extensive articles concerning the various subjects which they discuss, and the labor of compiling such an enormous amount of material (for the book is a large one of nearly 600 pages) must have been very great. The present volume begins with the subject of Dislocation and closes with the discussion of Infantile Myxedema.

**The International Medical Annual and Practitioner's Index for 1899.**

This, the seventeenth, issue of the Medical Annual comes to us possessing the many good characteristics of its predecessors. The book is designed, as most of our readers probably know, to give a brief résumé of the important points which have been gathered together from medical literature during the year 1898. It opens with a dictionary of new remedies, representing the therapeutic progress for the year, by Dr. Murrell of London, and closes with a brief monograph upon pathogenic bacteria in the human subject by Shattuck, which is illustrated by a number of chromolithographs designed to show various bacteria, the Widal reaction, and in general describe the microorganisms under consideration. While there is no particular part of this book which seems to us worthy of mention above another, it is altogether a most creditable summary of medical literature, and the seventeenth volume deserves the success obtained by its predecessors.

**Encyclopaedie der Therapie.** Herausgegeben von Oscar Liebreich, Dr. Med. Unter mitwirkung von Martin Mendelsohn, und Arthur Würzburg.

Berlin: Verlag von August Hirschwald, 1899.

This volume of Liebreich's Encyclopedia, which we have reviewed during the past four years in the Therapeutic Gazette, extends from the subject of Mammary Neuralgia to Pharyngitis, and covers 320 pages. It will be remembered that although it is entitled an Encyclopedia of Therapeutics, it is in reality an encyclopedia of medicine in general, and deals with subjects so distantly connected with therapeutics as mediastinal tumors. The present volume is exactly like its predecessors in scope, and contains articles by such well known men as Zuntz, Lesser, Liebreich himself, Riess, and Eulenburg; and when it is stated that these articles are creditable to the authors, and we remember the high standing of these writers in German literature, it can be readily understood that the volume is worth possessing by those who are able to read German.

Scarcely two years ago we took pleasure in reviewing the first edition of Dr. Bishop's book upon Diseases of the Ear, Nose, and Throat, and Their Accessory Cavities. As we pointed out at that time, the book is almost too freely illustrated, if that is possible, and certainly no one can say that it does not represent the author's individual ideas, for it is emphatically, at least in certain portions of it, a mirror of his views. On the other hand, there are portions of the work which are thrown together in a more careless way than we would expect to find in the second edition of so useful a manual; notably is this the case in the chapter which deals with the use of antitoxin in diphtheria, where the author has provided the reader with abstracts of the writings of others instead of simply quoting other authors and summarizing literature in a general way.

The present edition has been entirely reprinted in smaller type, which is, however, of excellent size, and contains much more text to the page than its predecessor. Some of the colored lithograph plates which illustrated the first edition, and which were evidently taken from Dr. Sajous' book on this subject, have been replaced by others which are quite different in their appearance, and which,
while they illustrate very well indeed the facts which the author desires to illustrate, do not possess the natural appearance of the earlier ones. The earlier book contained less than 500 pages; this contains 551, and as we have said, there is much more material to the individual page, so that the second edition is considerably larger than the first.

This second edition is considerably larger than the first, and is designed to represent in every detail the present views which are generally held by advanced obstetricians in regard to obstetrical surgery and the puerperal state. The book is well printed and well illustrated by figures from life and by original woodcuts, which illustrate various normal, pathological, and operative conditions. The index is, however, incomplete.

The fashion at the present time of illustrating books by means of photographs does not always give the most information to the reader, for in these photographs certain anatomical details are frequently lost, and the absence of color prevents differentiation between various tissues. Thus in the present volume, illustrations showing the method of expressing the placenta and of catheterizing a woman do not add really very much to the value of the text, and Plate 37 is particularly susceptible to this criticism.

We have read with interest what the authors have to say in regard to the use of ergot in labor. They believe that when the physician is satisfied that the uterus is empty, ergot should be administered in the dose of one drachm by the mouth—we presume in the form of fluid extract. They recognize, however, that the necessity for the administration of ergot is disputed on the ground that contraction of the uterus ought to take place physiologically; but on the other hand they believe that women rarely approach and pass through labor in a strict physiological manner, and that therefore this drug, which they think can do no harm, assists in maintaining the contraction of the uterus and thereby hastens involution. We are glad to note that they emphasize the fact that during labor this drug has no place. Ignorance of this fact has produced a vast amount of harm; it is only, as they say, when the uterus is completely empty that the administration of this drug is justifiable.

In the treatment of uterine inertia the authors recommend the use of twenty grains of quinine by the mouth or thirty grains by the rectum, in addition to uterine massage, and if the exhaustion is profound and the fetal heart weak, the application of the forceps. As is well known, the use of quinine is believed by some eminent obstetricians to be useless and prone to cause hemorrhage. However, this is a disputed point.

We can most cordially recommend this little manual of about 150 pages to our readers. It costs one dollar and contains adequate descriptions of practically all the newer remedies, including their synonyms, sources, methods of preparation, tests, solubilities, incompatible medications and doses as far as known, together with sections on organotherapeutic agents and indifferent compounds of iron. After the name of each chemical substance its formula is given, and the text affords us a most excellent summary of valuable knowledge. While it is of course true that many of the remedies named are not of great value, it is a most useful book to have at hand for reference.

A number of years ago Professor Riggs, of St. Paul, prepared for American students a translation of the earlier German edition of Professor Edinger’s well known work upon the Anatomy of the Central Nervous System. The present edition, which is prepared from the fifth German edition by Prof. Winfield S. Hall, with the assistance of Dr. P. L. Holland and Edward P. Carleton, all of whom are teachers in Chicago, is a great improvement over the earlier editions, largely because Professor Edinger has embraced the opportunity of improving his original German work within the last few years.

The present volume is a large octavo of 450 pages, well printed, and contains 258 illustrations designed to render lucid the anatomical facts which are stated in the text. If we remember rightly, when we reviewed the first American edition of this work we
expressed our regret that in reproducing the illustrations the lettering of the cuts had not been changed into English, but that the German anatomical terms had been retained. This objection has to be sure been set aside to a certain extent by the legends which are attached to some of the illustrations, in which translations of the German words are given; but on the other hand certain illustrations marked with German anatomical terms are not provided with such translations, and to those who are not familiar with German literature this may cause some difficulty in studying the matter, which is by no means easy to the ordinary student. At the same time, we cannot read the volume without being impressed with a fact already familiar to those who are in touch with neurological literature, namely, that Professor Edinger has provided us with a valuable contribution to medical literature, and one which should be in the hands of all those who are interested in neurology.

We congratulate the translators upon the excellent work which they have done, and upon their careful preparation of the text for American readers.

Materia Medica and Therapeutics. By J. Mitchell Bruce, M.A., M.D.

This is an advanced edition of Dr. Bruce’s well known little summary of Materia Medica. It is not designed as a practitioner’s handbook, but as a student’s vade-mecum in which the names, origins, actions, and toxicology of important drugs are discussed. Careful descriptions are given of the physical and chemical characteristics of the various substances, and it is because of these concise and lucid characteristics that the book has proved one of the most successful contributions to therapeutic literature that we know of. The concluding part of the work deals with general therapeutics and the foundations of rational treatment, and is exceedingly valuable, being practically a general discussion of the rules governing therapeutic procedures in the treatment of various diseases.

As Dr. Park well says in his preface, it is extraordinary that a second edition of a work of this character should be called for within a year after the appearance of the first, and it illustrates the fact that the medical profession was in need of such a summary of historical matters medical, and also that they are desirous of learning something concerning the earlier history of medical affairs in Europe and America.

As we pointed out in our review of the first edition, the book not only deals with those individuals who may be truly called the “fathers of medicine,” but also with many of the eminent medical men of this century in England and America; and the last chapters are illustrated by pictures of Benjamin Rush, George B. Wood, R. Dunglison, the elder Flint, Physic, Sims, and Agnew. A picture is also given of the first administration of ether as an anesthetic, in the Massachusetts General Hospital. Naturally a picture of Lord Lister accompanies the article upon antiseptic surgery.

Ann Arbor: George Wahr, 1899.

Dr. Novy has the knack of preparing facts in such a way as to make them prove very useful to students, and the second edition of his little manual on Bacteriology will increase his reputation as an easy writer and as a good teacher of bacteriological technique.

The present volume contains the necessary illustrations to render the experiments he suggests entirely clear, and opposite most of the descriptions of important microorganisms is placed a blank page upon which the student is supposed to draw the microorganism which he is studying. In other words, the book is designed not simply as a description of pathogenic and other microorganisms, but also as a working manual for the laboratory. It seems to us to meet in every way the requirements of such needs in teaching, and we believe that the second edition will be even more successful than the first.

The Medical Complications, Accidents, and Sequelae of Typhoid or Enteric Fever. By H. A. Hare, M.D., B.Sc. With a Special Chapter on the Mental Disturbances Following Typhoid Fever, by F. X. Dercum, M.D.

This is an octavo volume of a little less than 300 pages devoted to the subject named in the title, and considers cases occurring in the author’s practice, and also a discussion of the very large literature which exists at the present time concerning this very interesting disease.

Typhoid fever occurs in so many aberrant
forms and presents so many puzzling manifestations that in many instances it fails to correspond in any way in its course to the classical descriptions in text-books, and this book is designed to throw light upon such complications.

There are very few books which undergo the process of translation which are sufficiently popular to attain the honor of second editions in this country, and when it is considered how many excellent books on ophthalmology have been written by English and American physicians, it is surprising that even such a useful work as that of Professor Fuchs should have been so successful. Doubtless a large amount of this success depends upon the careful work which has been performed by the translator and editor, Dr. Duane, who is favorably known in America not only to ophthalmologists in particular, but also to the medical profession in general.

Much space of the book is saved from time to time by printing comparatively unimportant matter in small type. The illustrations, as a rule, show what they are intended to show, although they are not as well executed as we are accustomed to see them in American books at this time.

We are glad to see that the use of antitoxin is recommended in diphtherial conjunctivitis, although, as is well pointed out by the editor, this condition is rarely met with in America. We doubt not that this edition will prove as popular with the profession as its predecessor.

A few months ago a small brochure with a pliable cover came to our hands with the title borne by this volume, which is an octavo of a little over 100 pages, and is the second edition of the little handbook to which we have just referred. The demand for the earlier edition has caused the author to give some care to the preparation of the text, which has also been enlarged.

A large part of the present volume deals with the changes which appear in the skin of the hand in the various forms of skin disease, and the rest of it is devoted to the changes in the contour and character of the hand in various pathological conditions. The volume closes with quite a copious bibliography on such diseases as acanthroplasia, acromegalia, acroparesthesia, and other comparatively rare diseases involving the hand. Quite a full index completes the volume.

This is an exceedingly useful little book of about 100 pages, the function of which is well described in its title, namely, to bring to the hands of medical men information about their legal status, in the various States of the Union, and about the legal relations which they hold with patients and other practitioners.

Various ruling cases are cited which are designed to establish precedents for legal decisions in regard to the matters under discussion. The price of the book is fifty cents, and it is well worth purchase by every physician.

CLINICAL LECTURES ON NEURASTHENIA. By Thomas D. Savill, M.D. London: Henry J. Glaisher, 1899.

Dr. Savill is already well known to medical readers, as he has already published a small volume upon Epidemic Skin Diseases, and is about to bring out a small handbook upon the Diagnosis, Prognosis, and Treatment of Diseases of the Nervous System. The present small octavo volume, of a little over 135 pages, consists in part of lectures which he delivered in a postgraduate course in 1891, and again in other lectures which were delivered during the years 1897 and 1898. Some of them have already appeared in the Clinical Journal. Dr. Savill’s object in printing these lectures is to present in as clear and lucid a manner as possible his views in regard to the difficult questions which arise in the diagnosis of neurasthenia from symptoms produced by distinct and true pathological changes in the nervous system.

It is well known to those of experience that at times the symptoms of neurasthenia ape those which are produced by true nervous lesions in a manner which is difficult to differentiate. Dr. Savill seems to have successfully considered the various points which are necessary in the study of these cases. The text closes with a list of the more important contributions to the study of neurasthenia which have been made by American and foreign authors and with a copious index.

This addition to the rather copious elementary literature on anatomy will be fairly well justified by the illustrations alone, which are in the main admirable reproductions of photographs from dissections. The viscera and the relations to the surface of the body have been accorded the most prominent place in illustration and description. The study of the bones and of the joints, and of those minute parts which require special preparation for the dissection, has intentionally been omitted. The book seems excellently arranged for the student, and should serve as a help in the dissecting-room. The index is particularly to be recommended, on account of its accuracy and completeness.

Correspondence.

LONDON LETTER.

Since our last letter the first volume of "A Manual of Surgical Treatment," by Messrs. Watson Cheyne and Burghard, both surgeons to King's College Hospital, has come to hand. The work is to be in six volumes, of which the remaining five will be issued at intervals of not less than six months. The work is in no sense a dictionary, and only aims at recording those methods that have commended themselves as best in the daily practice of the writers. One great merit of the volume before us is that the patient is not, as in most treatises of the kind, relegated to oblivion as soon as he is removed from the operating table, but a great deal of attention is lavished on the details of after-treatment. If the remaining volumes maintain the high standard of the first, the authors will assuredly have made a very substantial addition to the surgical library of every class of practitioners. The work is to be published in America by Lea Brothers & Co., of Philadelphia, and each volume may be had for the modest outlay of three dollars.

Dr. Hale White made a further communication to the Clinical Society on "Three Cases of Right Colotomy for Chronic Colitis." The first case was that of a woman with membranous colitis of twenty years' standing, which had brought her to the last stages of exhaustion. The general tenderness of the colon pointed to extensive disease. From the time of the colotomy she rapidly gained ground. The artificial anus was closed after a year, and now a year and a half later the patient is to all intents and purposes in perfect health. In this, as in the succeeding two cases, the colotomy was performed in two stages, and the formation of membrane ceased immediately the bowel was stitched to the skin, and prior to opening it. From this Hale White contends that the formation of membrane is to some extent a neurotic phenomenon, susceptible of reflex inhibition, and certainly the clinical history of these patients warrants this suggestion. The second case presented all the features of the first, but the symptoms were only of one and a half year's standing; four months of perfect rest to the colon restored the patient to perfect health. The third case, that of an adult male, was treated by cæcotomy with equally good results as regards the restoration of health, but he served to illustrate one disadvantage of cæcotomy as against right colotomy in that fluid feces escaped from the wound when he stooped at work. Another drawback of cæcotomy is that it is almost impossible to prevent some feces finding their way into the colon. In none of the cases was it found necessary to wash out the bowel from the artificial to the natural anus. Six months seemed to be the minimum period for which the artificial anus should be left open, and as there was no difficulty in closing the orifice even after much longer periods, it was desirable to rest the colon for as much as a year. Hale White strongly recommended right colotomy for severe cases of the following conditions: (1) intractable membranous colitis; (2) all forms of chronic ulceration of the colon that had resisted prolonged medical treatment (cases of chronic dysentery were in all likelihood amenable to this line of treatment); (3) cases of idiopathic dilatation of the colon. In the discussion that followed the paper, Charles Symonds mentioned a case of chronic ulceration of the rectum of a similar type that he had relieved by stretching the sphincter ani.

At the same meeting of the Clinical Society an interesting discussion was carried on as to the treatment of chronic empyema of the maxillary sinus between the advocates on the one hand of simple drainage through a tooth socket, and on the other hand the champions of more radical measures. The
whole question appeared to turn very much on the nature of the pathological condition. Semon and St. Clair Thomson were of opinion that tradition was correct in referring the very large majority of cases of suppuration in the maxillary antrum to dental trouble. St. Clair Thomson recorded a case of from two to seven years’ duration, that had been completely cured in eight weeks by simple drainage by a spiral drainage-tube through an alveolus. Eve and Hovell, on the other hand, maintained that in a very large number of cases the condition was due to papillary outgrowths from the lining membrane of the antrum, so abundant in some cases as to completely fill the chamber and occlude the outlets. They urged free opening of the antrum through the canine fossa, so that the cavity could be inspected and the growths removed. In some cases they had found it necessary to make a counter-opening through the inner wall of the antrum at the level of the floor of the inferior meatus. The cavity was first packed with gauze and afterwards treated by antiseptic irrigation. The general feeling of the meeting was strongly in favor of the established procedure of first attempting simple drainage through the alveolus, combined with daily irrigation of the cavity with some simple alkaline lotion. The latter process was one that could easily be entrusted to the patient himself. Even in the cases of polypoid outgrowth, which it was generally agreed were extremely rare, there could be no objection to a preliminary trial of this method, which in no way precluded subsequent recourse to the more radical procedure, if that became necessary.

Dr. Leslie Phillips, of Birmingham, writes zealously in favor of antipyrin as a curative drug in cases of nocturnal incontinence of urine. There is, of course, no novelty in the employment of this particular drug for the condition in question. A very superficial survey of the pathology of enuresis will demonstrate the futility of any drug for all cases. We can hardly conceive of a single remedy alike applicable to oversensitiveness of the bladder, to weakness of the sphincter, to hyperacidity of the urine, and to a riotous nerve system. To trust to any drug in so complex a condition is to court failure, and contrariwise, we are of opinion that many drugs will be found useful, but only as adjuncts to other and more important general measures.

Dr. Kirkpatrick read a paper before the Royal Academy of Medicine in Ireland on "Room Disinfection by Formic Aldehyde." The method employed was to vaporize ten-grain formalin tablets in a Zimmerman’s “alformant” lamp. He showed that the process, while extremely simple, was far more effective than disinfection with such gases as sulphurous acid, bromine, and chlorine. A more detailed report was communicated by Dr. Littledale of actual experiments on test objects such as threads steeped in emulsions of various organisms. These threads were variously exposed, either free, or wrapped in filter-paper, or concealed in the pocket of a coat or between the leaves of books. Nine hours’ exposure completely devitalized all those freely exposed, so that no growth could be obtained on nutrient media, while those more closely concealed seemed hardly to be affected at all. One experiment with sputum is of special interest from its bearing on disinfection of tuberculous material. Sputum was openly exposed on cover-glasses, on which it had been let dry in the oven at 37° C., and after exposure for nine hours no growth took place in broth for two days—that is, until the surface layer digested off and the deep surface was exposed. In dried pus, exposed on gauze, the effect was far more destructive.

In an admirable article in the current number of Brain, Dr. James Collier has investigated the correctness of Babinski’s “toe-phenomenon;” together with other conditions of the plantar reflex. Substantially he confirms the observations of Babinski. He finds that in almost all cases of lesions of the pyramidal tracts the form of plantar reflex is changed from the normal adult flexor type to a type closely resembling the infantile extensor response. In infants, up till the age of learning to walk, the succession of contraction of muscles in the plantar reflex is entirely different from that of the adult; the adult type seems to be acquired along with full volitional control over the legs—that is to say, usually between the second and third years. In lesions of the pyramidal tracts this change of type of the plantar reflex is one of the first signs to appear, and the last to disappear when the lesion is temporary; in some cases it is the only unquestionable objective sign. This form of reflex is never found under other conditions, and is therefore a most valuable indication of structural change in the pyramidal system. With regard to the condition of the normal plantar reflex during sleep, he finds that the reflexes are diminished, but the infantile and adult
forms respectively are preserved, except in some children up to the age of twelve years, where in deep sleep the infantile form of reflex return. In cases in which the cord is completely severed transversely, the extensor reflex response is the only reflex phenomenon present in the lower limbs. This extensor reflex is never present in functional cases, although the flexor reflex response may be absent or difficult to elicit. This phenomenon, therefore, is a guide of first importance in distinguishing functional paralyses from lesions of the pyramidal systems. In tabes and peripheral neuritis, in cerebral and cerebellar tumors, not involving the pyramidal system, in neurasthenia, chorea, paralysis agitans, poliomyelitis, myopathy, and sciatica, the reflex is present in the flexor response.

Dr. Collier has also investigated the causation of pes cavus in spastic states. He shows conclusively that Duchenne's theory, that the pes cavus of spastic conditions is due to weakness of the interossei, is untenable; the condition is, however, intimately associated with the extensor response in the plantar reflex, and is produced by a state of reflex hypertonicity preponderating in those muscles which respond most vigorously in the plantar reflex. In all such cases of pes cavus evidence of increased tone in certain muscles can be demonstrated.

PARIS LETTER.

At a discussion that took place at the Society of Surgery on the 10th of May, the treatment of tuberculosis of the testicle was brought up and examined by several of the most eminent members of that body. Dr. Félixet, surgeon of the Paris hospitals, began by stating the method he employed in children, and which he has been using during the last fifteen years. As the skin of the scrotum does not give a good line of suture, he makes the incision back of the scrotal sac, near the perineum. The testicle is pushed back and an anteroposterior incision is made half-way between the middle line and the genito-crural line. This incision is two centimeters long for children and four or five for adults. The cremaster is cut in part and the testicle is enucleated. The mass is drawn down as far as possible, and two artery-forceps are placed as high as possible on the funiculum, and removed after forty-eight hours. Cicatization takes place in a few days. When ulceration already exists on the scrotum an incision is made around the latter and the same method is carried out, two or three sutures being placed on the skin. The speaker said he would try Doyen's method of "broiement" crushing of the arteries.

The subject of castration in tuberculous lesions is sub judice, some authors, like Dr. Lejars or Dr. Quénu, being adverse to such radical measures.

Dr. Quénu spoke on this subject, and said he thought it better to keep as much as possible of the testicle unless this organ was completely invaded. Where the lesions were localized, incision of the foci and cauterization with chloride of zinc are indicated. In case the epididymis was invaded, resection of the morbid part must be carried out. In subacute lesions opening of the abscess and cauterization were to be recommended.

Dr. Nimier, army surgeon, Dr. Lucas Championnière, Dr. Reclus, and Dr. Théophile Anger were of the same opinion as Dr. Quénu, and preserve as much as they can of the testicle.

On the 17th of May this question was taken up again by Dr. Potherat, who said he had always seen tuberculosis supervene in the other testicle after castration. Such a result seems to have been the case with a number of surgeons, and this recurrence of the disease takes place more or less rapidly. Castration to be effective would necessitate the removal of the vasa deferentia, the two vesicles, and the prostate. Besides, nothing demonstrated that the infection takes place from the testicle towards the prostate, and it would be rash to admit that castration could influence the lesions of the prostate. The speaker concluded by saying that from a moral point of view castration was not to be recommended, and to his mind the best treatment consisted in removing all foci with the bistoury, and suturing if possible.

Dr. Bazy, surgeon of the Beaujou Hospital, showed a patient who had been castrated on one side only, and in whom there was already infection on the other side.

Dr. Monod described his treatment of hemorrhoids, which was different from that of Whitehead. Two separate purgatives were given in succession, but no enema. Chloroform is used as the anesthetic, and dilatation made with Trélat's speculum. The hemorrhoidal excrences are then seized with clamps, which are placed in a direction parallel to that of the rectum. All the tissue
in front of the clamps is then removed and sutures made through the mucous membrane. No cutaneous-mucous membranes were thus obtained. The results had been excellent. Dr. Reclus said that his method resembled very much that of Dr. Monod, but he used cocaine instead of chloroform. Drs. Pozzi and Fillaux said they preferred to use the thermocautery. Dr. Pozzi gave as reasons for this course the fact that narrowing of the anal orifice was apt to supervene after excision of the mucous membrane.

The formula employed by Dr. Lucas Championnire in the treatment of burns may be of interest. He uses the following ointment:

- Vaselin, 100 grammes;
- Essence of thyme;
- Essence of origanum;
- Essence of verbena;
- Essence of geranium, 44.0.25 centigrammes;
- Naphthalate of soda, 1 to 5 grammes.

The following is the treatment used by Dr. Grasset, the celebrated neurologist of Montpellier, in the treatment of emphysema:

1. Twenty days every month give iodide of potassium 10 grammes, water enough to make 300 grammes; one large spoonful at each meal.

2. The next ten days take at each meal a spoonful of arsenate of soda 10 centigrammes, water 300 grammes.

3. Every week or every ten days take one going to bed a pill of 10 to 15 centigrammes of aloes.

4. Suppression of tobacco and alcohol. Milk at each meal.

5. If possible compressed air baths.

At a recent discussion at the Academy of Medicine, the question of the treatment of cysts of the liver was brought up, and Dr. Dieulafoy, professor of clinical medicine at the Hôtel Dieu, spoke on this subject. The question was to decide whether it is best to tap or to perform an operation. In the simplest cases, that are quite recent, it is sufficient to tap them. However, this very simple operation may be followed by the most untoward results, such as syncope and urtication. Dr. Chauffaud has cited a case where a simple exploratory puncture had been followed by urtication, status epilepticus, and death in twenty-five minutes. In such cases it is readily conceived that there being an excess of liquid in the cavity, there is filtration through the orifice.

Laparotomy, according to surgeons, is a very benign operation in such cases.

Dr. Dieulafoy comes to this conclusion:

First, in old cysts that may have suppurated, degenerated, or which have adherences, laparotomy is to be resorted to; secondly, simple tapping with aspiration in recent uncomplicated cases is advisable; thirdly, once the trocar is in, one should remove as much as possible of the liquid, and take care not to leave any quantity. In this way all accidents are obviated. Dr. Dieulafoy said he did not believe in using injections of various antiseptics, such as corrosive sublimate, as is recommended by Baccelli.

The question of sanatoria is of course being very much discussed at present in France, and at the Society of Therapeutics a certain number of resolutions showed the drift of medical opinion on this subject. Far from carrying out the system of large sanatoria such as those established in Germany and Switzerland, medical men in France seem to prefer small sanatoria with twenty to thirty beds, or even a smaller number, where the physician in charge will be more directly in contact with his patients. The following resolutions were passed:

The treatment by sanatoria as a means of insuring hygienic discipline and dietetics is the best.

Sanatoria should be established in places where the climate is naturally suitable.

Small sanatoria with a restricted number of beds should be founded in France, in various climates, according to the needs of the patients.

The Society of Therapeutics considers it necessary to have stations so placed that after a summer cure a winter cure may be carried out in a resort not too far distant from the first.

On account of the infectious nature of the disease, admitted by physicians nowadays, the use of ordinary wards for consumptives should be forbidden. Speaking of the latter part of this resolution I can cite the Bouicault Hospital as being one where these ideas are carried out almost to perfection. The “B” Pavilion is exclusively given over to consumptives, and it is almost a small sanatorium in Paris. I intend in my next letter to give a description of this new hospital, which is the finest in France.

**WOUND OF THE HEART.**

To the Editor of the Therapeutic Gazette.

**Sir:** On August 11, 1897, I was hurriedly called to see a colored man, forty-five years old, six feet high, and weighing about 185 pounds,
who had been fatally stabbed some thirty or forty minutes before my arrival. At every heart beat there gushed from a small wound, directly below the left nipple, between the fifth and sixth ribs, a wave of blood. There was another wound ten inches long, extending from the angle of the eleventh rib downward and forward toward the linea alba, and through the external oblique and transversalis muscles. On passing the index-finger into the small wound lying over the heart a cut could be distinctly felt in the wall of this viscus, apparently entering the right ventricle. The external bleeding was checked, and the patient was stimulated with strychnine and nitroglycerin hypodermically. While the long wound was being sutured the patient regained consciousness; he called me by name, and gave an intelligent account of the conditions which led up to the assault made upon him. He lived for about two and a half hours after receiving his wound. The autopsy showed that the diagnosis as to the position of the heart wound was correct, and that it was large enough to admit the small finger.

Very respectfully yours,

J. O. Rush, M.D.

COLT, ARK.

TREATMENT OF CEREBROSPINAL MENINGITIS WITH ANTI-STREPTOCOCCIC SERUM.

To the Editor of the Therapeutic Gazette.

SIR: An epidemic of cerebrospinal meningitis prevails here in Kansas as well as in some other localities this spring, and I wish to report a case which came under my care—not that I can add anything new as to the history, etiology, or pathology of the disease, but to present the treatment which was resorted to in my case.

May D., a strong, robust girl of fifteen, was taken sick on the 28th day of April, 1899, and I was called to see her on the morning of the 29th, at 5 A.M., when I found her suffering with intense pain in the head, which she described as "throbbing pains;" neck rigid; head thrown back; temperature 101°F.; pulse 120; pupils dilated; and all the other symptoms of the disease. The patient very soon after this became unconscious, and the pulse very variable, ranging in an hour from 50 to 120, and was different every time it was counted. Dr. J. P. Lewis, of this city, was called in consultation, and by 11 A.M. we began the use of the antistreptococcic serum, giving ten cubic centimeters at that time hypodermically, and another injection of the same amount at 4 P.M. of the same day.

The next morning the patient was semiconscious, and ten cubic centimeters was again given. On the third day the serum was used, the mind at this time being perfectly clear. On the fourth day the fourth dose was administered, and on the fifth day the fifth dose, with a constant and marked improvement, so that on the sixth day the serum was omitted. On the seventh day, the right knee-joint being badly swollen and painful, ten cubic centimeters of the serum was injected into the lower limb near the knee. Previous to this I had injected it into the subcutaneous tissue of the back, over the scapula. In a very few hours after this last injection the pain disappeared, and the swelling of the knee subsided.

From this time on recovery was rapid and uninterrupted.

It has been sufficiently demonstrated that by using antistreptococcic serum, the streptococcus can be antagonized and an animal rendered immune against that particular germ, but whether the streptococcus is found in sufficient quantity in meningitis to justify the use of the antistreptococcic serum I do not know.

Weichselbaum claims to have discovered the germ of cerebrospinal meningitis, and calls it the diplococcus intracellularis meningitis. Whether this serum destroyed enough streptococci to make such a marked improvement in this case, or whether it destroyed the above germ of Weichselbaum, I cannot tell, but as the death-rate has been high in this epidemic and as this was a severe case, the effect was truly remarkable.

I believe that in the near future, with the aid of all the wonderful modern scientific appliances, together with the fact that some of the brightest minds in the profession are giving their entire attention to bacteriology, a serum will be prepared for each disease due to a specific germ, and that the serum will not only destroy the germ but render the person immune against that particular organism.

The serum used in my case was made by Parke, Davis & Co., and great care was used in the technique by sterilizing the needle as well as washing off the place of injection with bichloride solution and afterward sealing the needle puncture with collodion.

Topeka, Kas.

W. L. WARRINER, M.D.

TREATMENT OF SUMMER DIARRHEA IN INFANTS.

By A. Jacobi, M.D., LL.D.,
Clinical Professor of Diseases of Children in the Medical Department of Columbia University (College of Physicians and Surgeons), New York.

To avoid errors in hygiene and diet is the best preventive. The debilitating influence of persistent summer heat should be counterbalanced by improving the vitality and powers of resistance in the young. It is true no newly-born baby should be bathed in cold water, but the gradual diminution of the temperature of the water used for ablutions may go on until after a few months the healthy infant bears washing and friction with cold water perfectly well. During the hot weather it should be so treated several times a day. The clothing should be thin; those who perspire freely should have no linen next to their bodies, the claims of modern preparations of that material notwithstanding; cotton or thin flannel, both of which gradually absorb and give up perspiration, is preferable. In very warm weather a single loose gown is sufficient. No feather beds or pillows should be permitted, no heavy curtains. Surely the baby is better off in a hammock, the head being supported by a...
hair- or air-pillow. Babies in bed should have their positions changed from time to
time. Their mouths should be anxiously watched, a teaspoonful or more of water
being given after every meal; the washing should be done without clumsy rubbing; and
plenty of drinking-water, the quantity de-
pending on seasons and the temperature of the
atmosphere, should be allowed in the intervals between feedings.

This is not the place to prove for the
hundredth time what I have said a thousand
times before. I shall only repeat that "cow's
milk is not woman's milk" and not identical
with it. Sterilization or Pasteurization does
not change its character; they merely obviate
such dangers as result from the presence of
most pathogenic germs and from premature
acidulation. The substitution of sterilized
cow's milk for woman's milk as the exclusive
infant food is a mistake. Digestive disorders
such as constipation or diarrhea, and constitu-
tional derangements such as rachitis and scurvy,
are often caused by its persistent and
exclusive use.

The percentage of milk-sugar in woman's
milk is larger than it is in cow's milk; indeed,
it is so large that five per cent of the normal
feces of a baby consists of unaltered sugar,
though its change into lactic acid is very
rapid indeed. Under the influence of this
rapid conversion cow's milk turns sour
speedily. Not infrequently it is acid from
the first; it has been found to be so in the
udder; in most cases it is neutral. As soon
as milk is swallowed, though it was alkaline,
the milk-sugar is converted into some form
of lactic acid by the action of a bacillus, of
which there are three varieties, according to
This process, after the rennet of the stomach
has exerted its coagulating effect, together
with the gradual transmutation of fat into
acid, is the final cause of curdling. When
there is much—or too much—milk-sugar,
though some of it be not changed at all,
there is an opportunity for too much lactic
acid. That is mainly so in the puerperal and
in the anemic woman. Both of them secrete
milk with a superabundance of milk-sugar,
and their babies may suffer for that reason
only from obstinate diarrhea. Cane-sugar is
not so easily transformed; indeed, it is utilized
for the purpose of counteracting the
rapid conversion of milk-sugar (as also for
the preservation of articles of food in
general). Trade is not so slow to avail itself of
the results of organic chemistry as the med-
ical profession. Condensed milk remains un-
changed for some time on account of the
plentiful addition of cane-sugar, in spite of
the original presence of milk-sugar in it.
Therefore it is not at all indifferent whether
milk-sugar or cane-sugar be added to the
food of infants and children. I have always
insisted upon the selection of the latter for
that purpose. Even Biedert, than whom
there is nobody more inclined to be guided
in his reasoning and formulæ by the conscien-
tious imitation of chemical accuracy, em-

ployes cane-sugar in his cream mixture.
There is enough milk-sugar in every infant
food, containing as it does cow's milk and
farinaes, to supply the demand of lactic acid
required for digestion and for antiseptic
effects in the lower part of the bowels. More-
over, according to Pavy, cane-sugar, part of
which is absorbed, is in part inverted into
grape-sugar. That is why even the amount
of cane-sugar should be rather restricted in
quantity, particularly in cases of sickness.
In the sick the absorption of sugar is slower
than in the healthy. Besides, during most
diseases, particularly those of the alimentary
channel, there is an unusual amount of ferment
in the mouth and stomach. That is why a
moderate quantity of sugar only should be
given in such conditions, never in a concen-
trated form, and least of all milk-sugar.*

As far as other points connected with nor-
mal feeding are concerned, that being the
best preventive of summer diarrhea, I beg to
refer my readers to some one of my former
writings (the latest of which are Therapeu-
tics of Infancy and Childhood, 2d ed., 1898,
and "Cholera Infantum," in Twentieth Cen-
tury Practice of Medicine, xiv) and to insist
again upon the danger involved in crowding
artificially fed infants with fat (cream) and
the advisability of adding cereal decoctions
to the cow's milk, which must necessarily be
the main constituent of infant foods. The
presence of a diastatic element in the secre-
tions of the salivary glands of the newly-born
and in those of the pancreas of the very
young infant, which was known perfectly
well these twenty-five years, and also utilized
in my practice and teaching, is no longer

*On the other hand, the effect of sugar as a means of
counteracting some forms of chronic constipation in in-
fants, due to a relative absence of sugar and supersub-
dance of casein, becomes plain. It is a practice that I
have recommended these forty years. Some cane-sugar,
a teaspoonful or less dissolved in tepid water (or oatmeal
water), should be given before each nursing; it will often
prove the only remedy required for the regulation of the
constipated bowels.
entirely unrecognized and is becoming gradually appreciated, even by the profession of medicine.* Many new observations and experiments add to our former knowledge on the subject. Only lately A. E. Austin (Boston Medical and Surgical Journal, No. 26, 1899) found that ptyalin remains active through one or two hours and is not even interfered with by the secretion of hydrochloric acid, which is secreted after a non-albuminuous as well as after an albuminous test meal — thus confirming Th. Rosenheim (Centralbl. f. d. Med. Wissensch., No. 12, 1887).

Amongst the causes of intestinal diseases not only the quality but also the quantity of food should be considered. More infants get sick from overfeeding than from underfeeding. The demand for elimination, which has to be controlled mainly by the kidneys and by the digestive glands, is excessive; these organs are overworked, and still they cannot dispose of the refuse in cases of overfeeding. Fermentation and putrefaction take the place of digestion, and gastric and intestinal, beside constitutional, disorders are the results.

Summer diarrhea is no pathological entity. It comprises all forms of diarrheal discharges, from an acute intestinal catarrh (which may or may not have a tendency to become chronic) to follicular enteritis, and streptococcic and bacillary gastroenteritis (Booker, Escherich). According to the mildness or severity of the case, the main symptoms are excessive discharge of a mucous, a serous, or a fetid character; desiccation of the tissues and general anemia, leading to insufficient nutrition and thromboses; and absorption of toxins generated by cocci or bacilli.

When any of the above named forms of enteritis is complicated with any kind of gastric disorder which is apt to show itself in nausea and vomiting, the stomach should be emptied.

The irrigation of the stomach meets with almost no difficulties in the young; an elastic catheter (No. 20 or 30 French) is sufficient. In very rare instances the nostril (mostly the right) may be used. Salt water (7:1000) may be poured through the tube from a funnel connected with it, or from a fountain syringe, which is slightly raised above the level of the pharynx, and lowered when the fluid and stomach contents are to flow out. This salt water may be mixed with a disinfectant, either thymol 1:3000–4000, or resorcin 1:1000, or in cases of known hyperacidity with bicarbonate of sodium 1:200–500. The temperature of the irrigation should be that of the body when this is normal, cooler when there is a great elevation, or warmer when there is a reduction of the body temperature. Alcohol should not be added to the injection, because its mixture with water is liable to be rapidly absorbed by the stomach. On the other hand, when water is injected without salt, it causes osmosis of the body fluids into the stomach, sometimes to such an extent as to visibly increase the amount returning from the stomach. The irrigations should amount to 100 and more cubic centimeters in the nursling, 200 or 300 in the child, and should be repeated until the liquid returns clear. The tube should always be withdrawn quickly, so that irritation of the fauces may be avoided.

The intestines should be emptied speedily by purgatives and by enemata. The former affect the whole length of the tract, the latter the lower part, as far as it can be reached by irrigations.

Irrigation of the intestinal tract is mostly performed while the patient is on his back, or side, with gently raised hips. The nozzle of the irrigator (fountain syringe) or of the tube connected with a funnel is introduced a few centimeters beyond the internal sphincter. Long tubes are generally useless; even in the cases of adults, with normal sigmoid flexures, the reports of the introduction of a tube to a distance of from twenty-five to fifty centimeters should be accepted with caution, for stiff tubes are able to raise the intestine and may be felt in the hepatic region, while a flexible tube is liable to turn upon itself. That is more so in infants and children, in whom the sigmoid flexure is multiple and can rarely be passed by an instrument. In some cases it is advisable to raise the lower half of the body considerably, according to the method I have followed these thirty years, to reduce intussusception, and to support the abdomen by a soft pillow, while the face is turned to one side to facilitate respiration. While the anus is firmly closed the liquid is allowed to flow in from a slight elevation, from ten to fifty centimeters (four to twenty inches). A greater elevation raises the pressure to an unbearable point, and the gut is no iron pipe. A slight elevation will

*It is surprising how long it takes us to divest ourselves of our ignorance or of a prejudice; may be that the agility of the wholesale food manufacturers who availed themselves all over the world of the new facts developed by Zweifel, Korowin, Schiffer, etc., discouraged the profession to accept the principle on which part of their merchandises were compounded.
improve the tolerance of the intestinal tract, which may thus be filled to the ileocecal valve and beyond; in very exceptional cases even to the stomach. It is only an abnormal intestine, dilated in places, or bound down by previous adhesions, or abnormally sensitive, that resents the flow of the fluid by spastic contractions, or by pain or vomiting. The indication of a greater or smaller elevation is guided, in special cases, by the object to be attained. Part of the liquid—particularly when slightly saline—is absorbed, and sometimes very quickly. That is why when that is not desirable (mostly with the first irrigation when the cleaning of the gut is the only indication) the irrigator should be raised high. Then the intestine fills up more rapidly, and the return of the fluid, with the contents of the bowels, is more readily secured. From one pint (500 cubic centimeters) to two quarts of water should be used in the first irrigations. When it is desirable to secure retention and absorption of the fluid, in collapse, or when brain symptoms make their appearance, the later irrigations should be smaller. Tepid or cool water should be used when there is hyperthermy, water of the temperature of the body when this is normal, hot water when there is hypothermy with or without collapse. Medicinal agents may be added to the water; for instance, thymol or permanganate of potassium in 1:3000—4000 solutions, or subnitrate or subgallate of bismuth, of which one or two teaspoonfuls may be stirred up with a pint or a quart of water.

The addition of gum acacia to the injection, or the use of glutinous decoctions such as flaxseed instead of water is preferred by many when there is tenesmus. Starch injections (the starch to be boiled before being mixed) have the advantage of adding to the nutrition of the body by the facility with which the colon changes amyrum into dextrin, which will be absorbed. Part of the injected water will always be absorbed, fill the bloodvessels, and may prevent intracranial and other thromboses. Indeed, in many bad cases in which the cerebral symptoms of the "hydrencephaloid" condition have made their appearance, or are imminent, frequent injections into the rectum of a few ounces of warm fluid contribute considerably to the restoration of circulation.

Of medicines which are to empty the bowels, castor oil, in doses of from one-half to two teaspoonfuls, is in common use, and acts well. It should not be combined with an opiate, which finds its indication after the purgative has acted. Calomel in small doses, one-tenth to one-fourth grain every hour, until the discharges show its presence, or a single larger dose of one to three grains, deserves the credit it enjoys.

Not only vomiting, but uncomplicated diarrhea, indicates the withholding of food or drink for some hours. The introduction of water into the rectum furnishes enough fluid during this dangerous condition. The thirst will rather decrease than increase during this period of apparent starvation. Indeed, owing to the gastric excitation and the intestinal hyperperistalsis, there is no absorption of ingesta. After a reasonable time small pieces of ice, which in the beginning would increase peristalsis, or a teaspoonful of boiled water (cooled) may be given, or the same quantity of a thoroughly cooked and strained barley-, or toast-, or rice-water. His favorable experience with farinaceous waters in the diseases of the infant intestine appears to have reconciled even Heubner to their administration.

At this stage of the ailment no milk is permitted, no breast milk, no sterilized or Pasteurized milk. "Under ordinary circumstances milk feeds babies, but in these extraordinary circumstances it feeds bacteria." It may take a few days or a week before the discharges cease to be thin and malodorous. After a few days the white of a raw egg, thoroughly beaten and mixed with barley- or rice-water, may take the place of milk. Meanwhile the thirst may be quenched by (now and then) a teaspoonful of a mild tea, or a few drops of good whiskey in a small quantity of barley-water may be given at safe intervals. A mixture that I have often recommended in writings and lectures, and which has rendered good service when the period of absolute starvation had passed, is as follows: One hundred and fifty cubic centimeters (five ounces) of barley-water, the white of one egg, one or two teaspoonfuls of whiskey, enough salt and cane-sugar to improve the taste. Of this a teaspoonful is administered every five or ten minutes. This is ample for sustenance, particularly when methodical rectal injections are employed. After a while sterilized or Pasteurized or boiled milk may be added, but not more than ten per cent of the mixture. As ever so many times previously these nearly thirty years, I can still recommend the mixture of hydrochloric acid with milk, according to I. Rudisch's formula. Two cubic centimeters (half a teaspoonful) of dilute hydrochloric acid is mixed with a pint of water, and this mixture with a
quart of milk; all of this is brought to a boiling point. If ever there be coagulation, it merely proves that the acid was in excess, by mistake. This is a mixture which is readily taken and digested by invalids and dyspeptics.

In most cases the contents of the stomach and the bowels are hyperac.id and require neutralization. Sodium and magnesium salts should not be employed because of their purgative effect. The carbonate or phosphate of calcium is preferable because it has no such effect, but the additional advantage of forming with the fat acids insoluble salts that act as protectors to the sore surfaces. From one-half to two grains may be given every hour, or two or three hours. Bismuth subnitrate or subgallate, with or without opium, and the alkali, in doses of one-half to two grains, may be given every two hours; it should soon cause the stools to exhibit a slate color. If any of these remedies be given in a liquid form they should not be mixed for the purpose of sweetening with syrups, but with glycerin. These small doses I find sufficient. Most infants may tolerate the large doses now and then reported in the journals, but some do not. Lead, gallic and tannic acid, alum, etc., are badly tolerated in acute cases, and are rarely required in chronic ones; these latter will now and then do well with fluid extract of coto (one-half to one minim every few hours), and many with nitrate of silver one-sixtieth to one-thirtieth grain (0.001−0.002) every two hours, in a teaspoonful of distilled water. It is mainly in the catarrh of the lower bowels that tannin, tannigen, or tanocol, in doses of from three to four grains (0.2−0.25) four or five times a day, acts well.

General collapse, or thorough exhaustion, with ashy pallor and depressed fontanel, demands stimulation, with hot rectal injections of a few ounces of water with from one to five per cent of whiskey (which should be of the best, because the fusel oil of poor brands is paralyzing rather than stimulating); subcutaneous injections of the saturated solution (1:2) of the salicylate (or the benzoate) of sodio-caffein, from five to ten drops once or repeatedly, or of $\frac{1}{16}$ or $\frac{1}{25}$ grain of sulphate of strychnine, or of a grain or more of camphor dissolved in a few drops of sweet almond oil, or of whiskey, or of a syrupful of tincture of musk. In urgent cases the subcutaneous infusion (7:1000) of sterilized salt water in quantities of from 300 to 500 grammes (ten to sixteen ounces), once or more times, may prove life-saving.

Great abdominal pain may be relieved by warm fomentations (water or poultices). They should be covered with oil silk, or a rubber cloth, and flannel, and must not moisten the clothing or bedding. When the pain is accompanied with fever, cool or cold applications should be made with the same caution, and changed when they become hot. In collapse the fomentations may be rather hot.

Opium relieves hyperesthesia, hypersecretion, and hyperperistalsis; it acts more slowly and more locally than morphine, and the latter should not be given. Opium finds no place in the incipient stages of dyspeptic and stercoraceous conditions with diarrhea, but when the bowels are emptied it deserves credit for the blessings it conveys. To condemn its use, because in a case of idiosyncrasy or of mistake on the part of a practitioner or an apothecary it proved dangerous (Which drug or food never did?) is fanaticism. A baby of six months may take safely of the camphorated tincture of opium, every two, three, or four hours, from four to ten drops ($\frac{1}{16}$ to $\frac{1}{8}$ grain of opium).

Putrefaction inside the gut does not reach the degree of that outside of the body, mainly because of the presence of organic acids and the relative exclusion of atmospheric air; but still it is going on all the time. It is active in the presence of much fluid, and is kept up by the presence of nitrogenous food. Even milk is no exception to the rule; generally, if at all, it is best when fermented, and mainly when deprived of its casein. Carbon hydrates interfere with putrefaction on account of their producing organic acids, and should be the principal food permitted for some time.

For their disinfectant effect calomel, bismuth, alcohol, creosote, salicylate of sodium, salol, naphthalin, betanaphthol, bichloride of mercury, and others have been recommended. The answer to the question whether disinfec-
tion of the alimentary canal may be accom-
plished by internal medication should not be left to bacteriologists, but to clinical observers, who are nearly unanimous as to the good effects that can be obtained by it. Rosor-
cin in doses of one-fourth grain or a little more every two hours, usually with some other indicated drug, has been of great serv-
tice to me. Its great solubility does not mitigate against its usefulness in the intestine, for though the stomach dissolves it, it does not absorb it any more than, with few exceptions, it absorbs anything. Salol, which
is insoluble until it reaches the alkaline contents of the intestine, and for that reason finds its natural indication in the demands of the lower part of the small and in the large intestines, may according to the age of the patient be given in doses of from one-half to two grains every three or four hours. There is hardly any of the above named drugs that has not been tried by every practitioner of large experience. Creosote is employed by many; alcohol in the shape of brandy, whiskey, or wine is safe in a number of cases where, besides antisepsis, stimulation is required; dilute hydrochloric acid improves gastric digestion in two ways, first by acting as an antiseptic, secondly by taking the place of the natural secretion of the stomach, which is liable to be defective in every morbid condition that results in exhaustion, anemia, and insufficient glandular function.

When the urgent symptoms of the disease have disappeared there is utter exhaustion, anemia, want of appetite, absence of the normal secretions and of the muscular powers of the digestive organs. To administer iron under such circumstances is not indicated; it is not dissolved and not absorbed; indeed, there is iron enough in whatever food is indicated and assimilated. There are two remedies which act as stimulants and tonics: strychnine, any of whose salts may be given in doses of one-sixtieth grain or more daily, in divided doses; and orixin, the tannate of which should be taken a few times a day, in doses of from one to three or four grains some time before meals, several times a day. That in the course of the disease, and during convalescence, fresh air—night air being superior to no air—should be furnished, and sojourn in the country be ordered, is self-understood. Indeed, many a case will die in the city in spite of whatever is done for it, and many a one which looked desperate will be quickly relieved and finally cured by cool mountain or sea air.

**TREATMENT OF SUMMER DIARRHEA IN INFANTS.**

**By J. P. Crozer Griffith, M.D.,**

Clinical Professor of the Diseases of Children in the University of Pennsylvania.

The questions often asked one, Do you use opium in treating diarrhea in infants? Do you use castor oil? Do you give antiseptics? and so on, can be answered in two words only, "That depends." Although there are a legion of remedies recommended for this disease, a long experience with its various forms has, I think, taught me that it is not so much the possession of a large variety of therapeutic measures which is needed, as it is the knowledge of how to choose any of them for the individual case. The physician who shows the best judgment in his selection may naturally be expected to obtain the best results. Not only is the nature of the diarrheal affection to be considered, but the stage of the disease also, and especially the condition of the patient. Finally, in dispensary practice there is a still more puzzling factor, viz., what therapeutic procedures one is able to have carried out.

The measures which I employ are few in number, but selected after much experimenting. In the early stages of simple acute diarrhea—call it by whatever name we please—the stopping of the supply of fuel to the fire is generally all that is needed. It is in such cases that free purgation is useful—by calomel, castor oil, magnesia, or other drug. As there is very liable to be some vomiting attending, my usual preference is for calomel, combined with bicarbonate of soda, in divided doses, for castor oil and other drugs are very apt to be rejected by the stomach. Combined with this treatment must be entire abstinence from the usual food. Withdrawal of all food is theoretically to be desired; but inasmuch as this, though good for the baby, is hard upon the sympathies of the mother, I generally order barley-water or gelatin-water in small amounts. Egg-water is useful where the condition of the child demands stronger nourishment.

By the second day of treatment we may generally conclude that the toxic substances have been removed, and that we have to deal with the remaining catarrhal condition of the intestine. As a rule purgatives are no longer needed, but the same plan of feeding should be followed. Should the diarrhea be still unabated by the second or third day of treatment, methods to check it may be required. After trial of many I still find nothing so generally useful as bismuth, giving four to five grains every two or three hours even to very young infants. Chalk mixture may be combined with this, with an aromatic water if there is much colicky pain.

In cases in which the diarrhea still tends to persist, other drugs may be used. Kino and krameria are useful remedies formerly much employed, but now largely replaced by newer astringents, such as tannalbumen and zannigen. I have found zannigen often disap-
pointing, but sometimes of service in cases which tended to prove obstinate.

In other rather persistent cases the administration of sulphuric acid is often of value. The antiseptic drugs have been found generally disappointing in my experience. Betanaphthol bismuth has sometimes seemed serviceable. Salicylic acid, resorcin, naphthalin, and others have all been tried. In combination with other remedies good often followed; used alone this was seldom the case. The inference was obvious. In some obstinate cases the continued administration of a mercurial in small doses is sometimes of service. In others, although only exceptionally, I have found the giving of castor oil daily during a few days apparently do good. Both of these are plans of treatment once very popular.

The question of the use of opium has been much discussed. After careful comparative tests in series of cases as similar as possible, I am convinced that this drug is often indispensable after the early days of the disease are over. Frequently its addition appeared to be the only means which would control the catarrhal state. It is sometimes necessary to give opium even early in the disease. There is the danger from this that the poisonous matters in the intestine may be locked up there and absorbed, and the general condition of the infant made much worse. On the other hand the child is sometimes weakened to such an extent by a profuse discharge from the bowel that the checking of this by any means possible is the first indication. I know of nothing requiring more judgment than the decision whether or not to give opium in certain cases. It is certain that the indiscriminate giving of opiates in the diarrhea of infants is to be deprecated.

The question of the use of lavage of the bowel is one of importance. A single large enema is sometimes very serviceable at the beginning of the treatment. As a rule, however, I find the methods already described preferable, except in those cases where from the beginning, or later, there is a great preponderance of mucus in the stools, although without evidence of an inflammatory condition being present. Here large injections of starch-water or of normal salt solution, given once or twice a day, will often do more good than any drug given by the mouth.

The return to the usual diet must be made with the greatest caution, as it is sometimes difficult to accomplish. No rules whatever for this can be laid down, except that the proteid element of the milk should at first be small in amount. Whey, cream mixtures, beef juice, egg-water, weak peptonized milk mixtures, and the like, all find their appropriate place in cases where the powers of digestion and absorption remain weak for a time. Alcohol and tonics in general are to be used when needed. No rules can be given.

Many of the cases of severe acute summer diarrhea appear to be instances of heat exhaustion. It is often a question whether we have to deal so much with an intestinal poisoning by bacteria, as with a profuse leakage from the bowel induced by excessively hot weather. A careful study of this matter during the heated terms of a number of years has convinced me that we err if we treat these cases with our minds centered on the idea of a bacterial cause alone. The coolest of clothing, the use of cool baths several times a day in suitable cases, the entire removal from hot weather, especially in cities, when practicable, or when not, the sending of the children into the parks, or preferably on the water during the daytime, are our best means of treatment. I have often told mothers not to return to the clinic until the weather was cooler, as I could not do as much for the babies as the cool air of the Delaware River could accomplish.

The treatment of enterocolitis is simple in its methods; difficult in the attaining of the desired results. Drugs given by the mouth have comparatively little influence. Bismuth in full doses is probably one of the best. Opiates may be needed to relieve pain and tenesmus, but have no distinctly curative action. On the other hand, local treatment is of the greatest importance. Douching the bowel once or twice a day with starch-water has stood me oftentimes in stead. The injection must be given slowly, and the infant made to retain as much as it can hold for some moments—best from a fountain syringe suspended not more than about two feet above the bed. Sometimes astringent enemata of tannic acid one-half to one per cent, or of nitrate of silver one-eighth to one-fourth per cent, act well, but I have often seen them increase the straining. The effect cannot be predicated; it can be determined only by trial. The addition of a small amount of laudanum to the enema is sometimes helpful. I have found enemata of a suspension of bismuth in mucilage of acacia sometimes of service.
THE THERAPEUTIC GAZETTE.

Of very great importance in this disease is change of air and change of diet. It happens not infrequently that babies seem to have lost their power to digest milk in any form. In such cases to give it at all is harmful, until recovery is well under way.

This form of diarrhea often lasts for weeks, and the general health suffers greatly, necessitating careful tonic and supporting treatment.

Infants developing enterocolitis in hospital wards had better be removed. Not only is their treatment there absolutely discouraging, but the disease is certainly often infectious and will spread to others.

Cases of what I can truly call cholera infantum do not very often come under my observation. The name is very commonly misapplied. It is well to remember that in this disease we are dealing not so much with a poison still in the intestinal canal as with one in the system. We have the symptom of profuse exhausting discharge from the bowel, and this symptom must be combated at once with opium in full doses. The other severe manifestations of this disease are to be treated symptomatically as they arise.

The condition of pseudomeningitis depending on diarrheal diseases is frequently seen. It must be treated according to circumstances. There sometimes arises a curious condition in which there is present apparently a paralytic condition of the vasomotor and, probably, pneumogastric systems, yet with no special simulation of meningitis. In such cases, without any exhausting diarrhea or evidence of intestinal decomposition, the child breathes constantly with great rapidity, exhibits flushing of parts of the body, has a rapid, feeble pulse, and may readily die promptly without one being able to tell just why. Undoubtedly this is a toxemic state. While not neglecting the condition of the bowel whence the trouble comes, our chief efforts must be directed to the nervous condition. Strychnine in full doses, nitroglycerin, digitalis, and atropine will aid us most.

What I have written briefly is not, of course, intended to cover the wide subject of the treatment of the diarrheas of infancy, but only to express the result of personal experience and observation. I must urge in closing what has already been indicated—that any methods detailed can have only a general application. The individual is everything, and the features of each case must be carefully studied to obtain good results.

TREATMENT OF SUMMER DIARRHEA IN INFANTS.

By L. Emmett Holt, M.D., New York, Professor of Diseases of Children in the New York Polyclinic.

It must be distinctly kept in mind that cases of summer diarrhea, so called, are not at the outset inflammations of the mucous membrane of the stomach and intestines, although inflammation of a serious character may afterwards develop. The initial condition is in the nature of an acute intoxication, which arises from the materials in the digestive tract. The circumstances which favor such a state of affairs are an arrest of stomach and intestinal digestion and the presence of food remains readily acted upon by the bacteria, which were there before, or which have been introduced with the food (usually milk) which has been taken. The damage done to the epithelial walls and afterwards to the other coats of the intestine, as well as the constitutional symptoms which form the familiar picture of a severe case of summer diarrhea, are both the consequences of changes taking place in the matter contained in the gastrointestinal tract. The inflammations developing in other organs, especially the kidneys, are also a result of the absorption of such toxic materials into the general circulation.

It being therefore the gastrointestinal contents which are the fons et origo of the trouble, it follows that the first indications for treatment are to stop all food, but especially milk, and to evacuate the stomach and bowels by the most certain, easy, and rapid means at our disposal.

Stomach Washing.—This is useful where vomiting is a prominent symptom, and is of value chiefly in cases seen early. In such it is well to use the water at a little higher temperature than usual—i.e., at 110° F., or even a little above this point. I see no advantage in adding anything to the warm water (which should first have been boiled) except a little bicarbonate of soda, where there is considerable ropy mucus in the matters brought up. The washing of the stomach must be thorough, nearly a quart of water being used, and allowed to flow in and out of the tube until it comes away quite clear. It is often well to leave three or four ounces of water in the stomach.

It is rarely necessary to repeat the stomach washing.

Intestinal Irrigation.—This is of very great value—I am inclined to think of more value
than anything else we can do for these cases, except perhaps to stop food. It is, however, of little avail unless properly carried out. Some reference to details may therefore not be out of place. The catheter used should be of flexible rubber, should have considerable resistance, and should be nearly new, as one much used soon becomes so soft and bends so easily as to make full introduction difficult or impossible. I prefer the infant's rectal irrigating tube (made by Tiemann & Co., New York), which is about twenty inches long, the usual size being that of a No. 18 American catheter, but a little heavier than catheters are generally made, and having an opening at the end as well as an eye on the side near the extremity. This tube does not bend easily upon itself, and when fully introduced reaches almost to the splenic flexure; in that position it is an easy matter to flush out the entire colon.

Instead of the fountain syringe I prefer a glass irrigator, which enables one to see at a glance whether the water is flowing steadily or is obstructed by bending of the tube or any other cause. The amount of force employed is of some importance; an elevation of the irrigator four feet above the patient is quite sufficient, and much more than this may be harmful. I prefer a saline solution (one drachm to the pint) at a temperature of 100° to 104° F. Water at a lower temperature often causes so much contraction of the muscular coats of the colon as to interfere with thorough flushing. However, after using three or four quarts of the warm water, I often introduce at the end, particularly if the patient's temperature is high, one quart at 65° or 70° F. This has a good tonic effect on the mucous membrane and has a favorable influence on the body temperature. It is by no means necessary to have all the water escape through the tube; on the contrary it is in most instances advisable to allow at least a pint to remain, for the system is usually suffering greatly from the lack of fluid resulting from the diarrhea.

If properly done, irrigation empties the colon and does it thoroughly; but this is soon filled again by the descent of materials from the small intestine. Such a descent seems greatly to be hastened by washing the colon. It happens therefore that in a few hours the colon may contain almost as much as when it was first washed out, and the irrigation must be repeated.

No one would think that he had done his duty when he had washed out a septic uterus once in twenty-four hours; and for similar reasons irrigation of the colon must be repeated in severe cases with high temperature and marked nervous symptoms at least once in six hours if we are to expect much from it.

The importance of washing out the colon and keeping it clean cannot be overestimated in relation to the production of serious intestinal lesions in the protracted cases. There appears to be a definite and constant relation between the situation of the intestinal lesions and the movement of the intestinal contents. In the jejunum and upper ileum, where the contents are propelled rapidly onward, serious lesions are never seen. When lesions are present, they are always situated where the intestinal contents are arrested and accumulate, viz., in the lower part of the ileum and the colon; while in the colon itself it is the caecum, the sigmoid flexure, and the rectum which suffer most.

Cathartics.—While distinctly less valuable than intestinal irrigation, they are of very great utility, particularly in the early stages of the attack. Only by them can we sweep downward the whole contents of the small intestine into the colon, where it can be reached from below. Castor oil, calomel, and the salines are the best. The oil is to be preferred in the subacute cases, where the stomach is very little or not at all upset. The dose must be liberal—a teaspoonful to an infant of six months, and this repeated in three hours. Calomel I usually order in tablet form in quarter-grain doses hourly, until six doses have been given. Of the salines, magnesia is to be preferred. The milk of magnesia is not usually vomited even by an irritable stomach, and may be given in teaspoonful doses hourly for four doses; or the solution of the citrate may be given in teaspoonful or tablespoonful doses every fifteen or twenty minutes until three or four ounces have been given.

In protracted cases there is an advantage in clearing the intestine once in four or five days with an active purgative.

Other Drugs.—The disposition to rely much upon drugs, especially of the class which are used to check intestinal discharges, is fortunately rapidly passing away. Opium, formerly given so large a place, should be restricted to the checking of exaggerated peristalsis after the character of the movements has ceased to be foul, and in fact has often become nearly normal. Small doses usually suffice for this purpose—i.e., to an
infant of six months, five drops of paregoric every three to six hours.

I am still of the opinion that bismuth is useful in these cases, and have found none of the newer preparations superior to the commonly used subnitrate.

With reference to most of the other drugs used in these cases, I must say that to my mind their value is not yet proven.

Diets.—It is impossible in the limits of this article to give more than a brief summary of the principles of feeding these children. In the cases with an acute onset the importance of stopping at once all food, but especially milk, has already been referred to.

For twelve hours, or perhaps longer, all food should be withheld and only cool, boiled water given, but given liberally. Next there may be tried whey, thin barley-water, egg-albumen water, weak mutton or chicken broth; later, beef juice and some of the melted foods. No milk should be allowed for at least four or five days in milder cases, and in severe ones it must usually be withheld twice as long. When begun, it should be diluted five or six times with water, and preferably peptonized. To do much good in these cases peptonization must be complete (two hours), and it is best done before dilution. A laboratory formula for a three-months baby would be: fat, 0.50 or 0.75; sugar, 5.0; proteins, 0.50 or 0.60.

The hygienic treatment of these children is equally important with the measures mentioned above, and includes frequent bathing, both for the reduction of temperature and the allaying of nervous symptoms, and change of air whenever possible from the city to the seashore or mountains. Careful disinfection of napkins in institutions should always be practiced, or we are almost certain to see a spreading of the disease. To this cause and to overcrowding are to be attributed many epidemics in institutions where the question of previous feeding has received due attention.

After all, it is preventive, not curative, treatment which gives the most satisfaction to the physician. This should embrace:

1. A proper application of the well established rules regarding infant feeding; for it is chiefly infants who have previously suffered from digestive and nutritive disturbances arising from a violation of these rules who furnish us with our severe and most of our fatal cases.

2. Careful inspection of milk in cities, and the exclusion of that the temperature of which when received is 60° F. or above; and closer supervision of those who sell milk than is now employed.

3. The adoption of means by which the poor in cities may be furnished during the summer with milk sterilized under competent supervision, either free or at a nominal cost.

4. The general employment of Pasteurized or sterilized milk as an infant food during summer; Pasteurized, among the better classes, where the procedure can be more intelligently done and ice is abundant; but sterilized, among the poor and in tenements, or wherever no ice is to be had.

5. The avoidance of all solid food during the summer in children who are under eighteen months old.

6. The prompt and radical treatment of all the milder forms of indigestion and diarrhea during the hot season.

In our management of infants suffering from intestinal disorders, the great importance of the adoption of energetic measures at the outset cannot be too strongly emphasized. Doing the proper thing in the first twelve hours of an attack is vastly more valuable than correct treatment during the whole of the succeeding week.

14 West 55th St., New York.

TREATMENT OF SUMMER DIARRHEA IN INFANTS.

By Louis Fischer, M.D.,
Professor of Diseases of Children in the New York School of Clinical Medicine; Attending Physician to the Children's Department of the German Poliklinik, to the Children's Department of the West Side German Dispensary; Consulting Physician to the Children's Department of the United Hebrew Charities, to the Messiah Home for Children, etc., etc.

It is a well known fact that children have a normal tendency to loose, liquid, and semi-liquid evacuations from the bowels. This is partly due to the anatomical condition of the intestinal tract, and secondly to the nature of the normal food—i.e., breast milk.

The peristaltic movements in a child are very active owing to their physiological development. Young blood-vessels and the lymphatic vessels are very permeable, and the transformation of the surface cells is active and rapid.

The peripheral nerves are superficial, more so than in adults, whose mucous membrane and submucous tissues have undergone thickening by both normal development and mor-
bid processes. The action of the sphincter ani is not very powerful. The frequency of acids (sometimes normal) in the small intestine gives rise to the formation of alkaline salts with purgative properties. Free acids, when found in the intestine, show that (1) the quantity of food is too large; (2) the quantity of the digestive fluid is too small, causing fermentation instead of normal digestion.

The diastatic effect of pancreatic juice is limited at an early age and undigested material is carried off.

Colostrum secreted after birth is apt to give rise to diarrhea. Milk containing too much fat or too many salts, as in anemia, is liable to produce the same effect.

The etiological factors can be briefly outlined as follows:

1. Food, improper quantity and quality of the same, be it breast milk or hand-feeding. It is a well known fact, cited by Jacobi among others, that breast milk can also cause this disease.

2. The most frequent cause is certainly improper bottle-feeding, wherein food unsuited to the infant’s digestive abilities is continued, in spite of nature’s effort to warn us, as frequently manifested by either vomiting or diarrhea, or both.

3. Milk from mothers suffering with tuberculosis or syphilis. Pregnant women, menstruating and all anemic women, secrete such poor milk that gastroenteric derangements are exceedingly common.

4. The influence of the weather on digestion, especially the extreme heat of summer.

5. Improper disinfection of the nipples after feeding, and consequent decomposition and formation of microorganisms, causing infection; all unsanitary conditions deleterious to the healthy child.

Having noted the various causes of summer diarrhea, chief among which is improper feeding and its resultant diarrhea, the first thing to do is to cleanse the stomach and bowels. This can be most readily accomplished by

**Stomach Washing.**—To do this, I take a No. 10 soft flexible (rubber) catheter, having more than one opening, and attach it to either a two quart glass irrigator or a two-quart rubber fountain syringe. It is far better to use rubber tubing and a glass funnel, as we can then easily watch the liquid enter, and it is also more practical, as it can be kept clean more readily. For irrigating the stomach I use the following solution:

- Table salt, 1 teaspoonful;
- Boiled water, 1 quart.

The above quantity for one washing, to be used until the gastric contents flow away clear. To introduce the tube, it is pushed through the mouth, gently but rapidly against the pharyngeal wall, into the esophagus, until the stomach is reached. It should not be anointed with oil, as we normally have so much mucus present that we have nature’s own lubrication. The No. 10 tube is for a child between six months and one year of age. Having introduced the tube, I raise the irrigator or funnel or fountain syringe, which has been previously filled with one quart of the salt solution mentioned above, and hold the same about one to two feet over the child’s head—no higher. The temperature of the water should be between 100° and 105° F. If there is severe irritability of the stomach, or a tendency to nausea and vomiting, then it is a safe plan to attach the catheter to a long tube, ending in a funnel, and using but one-half to one pint of the salt solution, allow it to enter the stomach slowly. By using the funnel we can siphon off the contents of the stomach by lowering the funnel below the level of the stomach. After emptying the same we can again fill the funnel, and allow the contents to flow into the stomach; and so this process of siphoning can be repeated until the gastric contents flow away fairly clean.

It is a good plan not to continue the washing of the stomach, unless urgent symptoms of gastric fermentation or possibly vomiting of food call for the same. It is my plan to wait at least one or two days and note the effect of the stomach washing before repeating it.

Having cleaned the stomach, it is a good plan to prescribe rest, and to insist on leaving the child several hours, without giving food of any kind. I usually order a small quantity of an alkaline water, either seltzer or Vichy, apollinaris water, or plain boiled (sterilized) water. A wineglassful of lime-water, several times a day, independent of food, is also advantageous.

In all forms of diarrhea milk must be discontinued. The details of feeding will be discussed later on.

When we find a decided objection on the part of the patients or their friends to the above method of cleansing the stomach, then we must resort to

**Drug Treatment.**—For this purpose a large dose of calomel, say one-fourth grain for a
child one year old, is given every two or three hours, until watery stools are produced, and this is followed on the succeeding day by two or three doses (a teaspoonful each) of castor oil. The tendency to constipation following a dose of castor oil makes it a valuable remedy in all forms of diarrhea. Bismuth is the sovereign remedy; I have used the subcarbonate, subnitrate, salicylate, and betanaphthol bismuth, and find the latter an extremely valuable preparation. In doses of two to five grains every few hours, mixed with a little boiled water, it not only agrees very well with children, but seems to exert a healing effect in that form of bacillary diarrhea which is met with in the acute catarrhal gastroenteritis.

Salol in doses of one, two, and three grains, for each year respectively, is another valuable remedy; so also is resorcin, in doses of one-fourth to one grain for a child one year old, three or four times a day. It is advisable not to add sugar for sweetening, but only glycercin; the latter, however, in very small quantities, as it has a tendency to loosen the bowels.

Nitrate of silver in doses of one-fiftieth of a grain for a child one year old, repeated every three or four hours, is valuable in some cases.

Tannalbin and tannigen in doses of from one to ten grains seem to act well in some cases, poorly in others, but are well worth trying in those desperate cases in which we change the drugs, if they are ineffectual.

**Hypodermic Medication.**—In forms of collapse, where constant diarrhea has drained the system, it is a good plan when the extremities are cold to give hypodermic injections of ten to twenty drops of whiskey. Sulphuric ether can also be administered hypodermically in the same dose as whiskey. Another valuable stimulant is musk; two to three drops of tincture of musk administered hypodermically every hour will frequently rouse the circulation.

When this form of treatment proves unsuccessful, and the condition of collapse continues, then a good plan is to resort to hypodermolysis. This consists of introducing a long aspirating needle (previously sterilized by boiling) into the loose connective tissue of the abdomen, and allowing several pints of the normal saline solution, containing about 7½ grains of table salt to a pint of water, temperature 100° F., to flow in subcutaneously. It is remarkable to note how much liquid can be introduced in this manner, and some of the most violent of cases of collapse will respond very rapidly. I have seen children who previous to this injection were pulseless suddenly brighten up, and within a few minutes show a distinct radial pulse. Too much care cannot be bestowed on the sterilization of every part of the apparatus, and the absolute cleanliness of the water to be used for this purpose.

**Rectal and Colon Flushing.**—It is advisable to irrigate the colon and rectum by placing the child on its left side, introducing a flexible rubber tube and anointing with carbolized vaselin. Having passed the external sphincter, I invariably allow the water to flow into the rectum in order to balloon the same, and then continue to push the tube beyond the rectum into the colon. A little difficulty is sometimes encountered, owing to the spasmotic contraction of the muscles, but if we wait a short time, using a little patience, the tube can be easily pushed into the colon. The method pursued is the same as described previously in irrigating the stomach, excepting that we do not seek to siphon off the contents of the bowels, but rather allow a pint or a quart of the warm saline solution to flush the bowels, and in this manner wash away as much of the offending débris as exists within the bowels. I have frequently used cold water, but I find much greater benefit from the use of a warm solution of the temperature of 100° F.

Besides table-salt solution, a one-per-cent boracic acid solution can be used, so also can a 1-to-10,000 solution of bichloride of mercury. A solution of ten grains of tannic acid to a pint can also be used, and a 1-to-1000 solution of nitrate of silver is indicated in other cases.

Some of our cases require irrigation once in twenty-four hours for one week, and others again are so greatly improved after one rectal washing that it is not necessary to resort to it again.

Starch injections, made by adding two teaspoonfuls of the ordinary starch to a teacupful of warm water of a temperature of 105° F., may be given. They are very advantageous, as the colon changes starch into dextrin, which is easily absorbed. Thus not only does the latter cleanse, but it is also nutritious. Large quantities of saline solution can be introduced directly into the circulation by means of cold washing, thus adding to the volume of the blood. I therefore lay great stress on this form of treatment, as one of the most valuable for this depleting condition.
Thromboses can frequently be avoided by these injections.

When severe tenesmus exists, painting of the lower end of the rectum with a two-per-cent solution of cocaine is frequently very advantageous. Prolapse of the rectum and anus can frequently be prevented by applying a strip of rubber adhesive plaster from one buttock tightly to the other, so that the buttocks will support the bowel and mechanically prevent its protrusion.

*Feeding.*—Milk in all forms is to be discontinued for at least one week, unless the child is breast-fed, and if the latter, then the breast feeding should be stopped for at least one-half to one whole day, and instead barley-, rice-, or farina-water can be substituted, no matter what the age.

To make rice-, barley-, farina-, sago-, or cornstarch-water, take a tablespoonful of either of the above to a pint of water and allow it to boil a short time, then strain through cheese-cloth, and add enough boiled water to make one pint in all.

*Flour Ball.* A small bag made of cheesecloth is to be filled with wheat flour, and suspended or immersed in a saucepan of water. This is to be boiled from six to twelve hours constantly. The flour becomes agglomerated into a hard mass, and is doughy only on the surface. It is then removed and allowed to dry, and after removal of the crust it is grated, and makes a whitish-yellow powder that is very nutritious. I usually commence with a teaspoonful to ten or twelve tablespoonfuls of water, with a pinch of salt and sugar, for one feeding. If it agrees well with the child, then I increase the quantity of the flour ball by adding a half-teaspoonful more every three days to the same quantity of water. If this agrees very well and the child seems to assimilate the food, then I usually, after one week of flour-ball feeding, substitute one ounce of cow’s milk for one ounce of water, so that the formula would be one teaspoonful of flour ball, four ounces of water, one ounce of cow’s milk, pinch of salt, and some lump sugar, for a child nine months old and older. This formula I have found eminently successful in the treatment of summer diarrhea, but I usually omit the milk.

A good plan is to feed with intervals of three and four hours between each meal, and if the usual amount of feeding was six or eight ounces, then it is a good plan to give but four or six ounces, or either rice-, barley-, or farina-water. Albumen-water, made by adding the white of a raw egg to a wine-glassful of sterilized water and a pinch of salt, is very good to allay thirst, besides adding to the nutrition of the child. Ice-cold tea (the ordinary black and green tea mixed) can be given *ad libitum.*

In using the starch enema for washing the bowel, the albumen of a raw egg, or the yolk of an egg or a few drops of expressed steak juice, can be safely added, provided we add a small quantity of pancreatin and bicarbonate of soda to predigest or peptonize it.

*Hygienic Treatment.*—Cold bathing or bathing in cold or lukewarm water, to which some sea salt has been added, is very advantageous; the child should be put into the largest and coolest room in the house, the temperature of which is from 68° to 75° F. If sea air is obtainable, then it is wise to remove the child to the seashore, or at least to insist on daily excursions.

Cold applications to the head and an ice-bag over the fontanel, cold towels changed every fifteen or thirty minutes over the abdomen, will tone up the nervous system in addition to reducing the temperature. I am a decided opponent to antipyretic drugs, and never use antipyrin or phenacetin, but invariably resort to hydropathic measures for the reduction of the temperature. Sponging of the body with alcohol and water is very grateful and refreshing, besides a good antipyretic measure. If cyanosis and cold extremities exist, then it is wise to resort to hot mustard baths, to stimulate the circulation.

The above is the plan that I have used and advocated for the last ten years. We cannot set up cast-iron rules; we must individualize and study each child’s digestion, the stools, note the weight (scales) weekly, and follow carefully each change of food until we are satisfied that we have the proper form of diet.

---

**TREATMENT OF SUMMER DIARRHEA IN INFANTS.**

*By Edwin E. Graham, M.D.,*  
Clinical Professor of Diseases of Children in the Jefferson Medical College; Member of the American Pediatric Society; President of the Philadelphia Pediatric Society.

During infancy and early childhood the mucous membranes are especially liable to become the seat of various lesions. The influence that dentition exerts is largely controlled by the child’s physical condition. Healthy children often pass through this dangerous period without any symptoms ref-
erable to the appearance of the teeth. In
delicate children dentition may and not un-
commonly does aggravate the symptoms aris-
ing from any disease. In these children it
must be remembered that the disorders oc-
curring during the period of dentition may
be due to this condition of weakened vitality
and not to the teething per se. The diagnosis
of teething diverts the mind of every one
concerned from the vital subjects of food, air,
and hygiene.

The non-specific directions concerning the
feeding of children often left by the attend-
ing physician constitute also a factor that
contributes largely to the so-called summer
diseases, marasmus and teething diarrhea.
The marked advances recently made in the
feeding of infants and children, the advan-
tages derived from the knowledge of how to
give milk of specific percentage and the adapt-
ing of this percentage milk to the weakened
digestive powers of the sick infant, is a matter
of vital importance, and the results obtained
are often favorable or otherwise in propor-
tion to the skill displayed in this modification
of the child's food to its weakened digestion
and assimilation. It should be remembered
that a nervous woman, overworked and
worried by household cares, cannot supply
suitable milk for a child. Under such con-
ditions rest for body and mind, with system-
atic outdoor exercise and wholesome food,
and an abundance of undisturbed sleep, will
often accomplish wonders. The diet of the
nursing mother should be carefully super-
vised. Excessive drinking of tea, coffee, or
alcoholic stimulants, the eating of dainties,
overeating, especially common in wet-nurses
who from the change in their surroundings
(from poverty to abundance) often are led to
eat to excess—all these are factors which
count against the rapid convalescence of in-
fants ill from any gastrointestinal disorder.

In the selection of a wet-nurse one should
be careful to exclude all possibilities of syph-
ilis and tuberculosis; she should be between
twenty-three and thirty-five years of age, of
a quiet, even temperament, and her breasts
should be well formed, hard, and firm, the
milk flowing readily upon light pressure, and,
when possible, its quality should be deter-
mined by chemical analysis. Much can be
learned by seeing the wet-nurse's own child,
as its condition, whether weak or strong,
points accordingly to a poor or good supply
of breast milk. The knowledge that milk is
a most fertile culture medium for germs of
all kinds, that milk is sterile as it leaves the
healthy cow, and that as ordinarily received
it contains dirt and filth from the cow's udder
and the milker's hands, that it is rarely or
never free from germs, and that numerous
cases of diarrheal disease have been traced
to the milk supply, should certainly cause
both patient and physician to insist on the
establishment of dairies from which clean
and good milk is obtainable. Cases of con-
tinued malnutrition following severe diar-
rhreal diseases are often with advantage given
non-Pasteurized milk. The plan suggested
by Seibert, of filtering the milk through a
thickness of one-quarter of an inch of moist
cotton, is sufficient to remove not only all
impurities, such as dust, dirt, cow's dung, etc.,
but also about seven-eighths of the germs
contained therein before filtration. The fil-
tration alters little if any the amount of fat,
proteid, and sugar present. Care must be
taken to allow the first few teaspoonfuls
filtered to escape, as this part of the milk
contains a large proportion of the germs that
escape removal.

Barley-water, lime-water, and sterile water
are used as diluents of milk, the two last
mentioned being preferable during the acute
stages of the summer diseases, the barley-
water being of service during the period of
convalescence for infants after their ninth
month.

Breast-fed babies during the acute stages
may be given a small quantity of sterile
water just before nursing, or the milk pumped
from the breast may be diluted and given.
If such milk is retained I believe more rapid
results are usually secured than when breast
milk is withdrawn, although many cases are
benefited by a complete withdrawal of milk
for the first few days.

Peptonization is often of signal service; we
can by its help relieve the strain upon the
digestive apparatus and still give a fair or
adequate amount of nourishment.

The influence, etiologically, that microor-
ganisms exert in the production of the sum-
mer diarrhea of infancy is admitted by all.
The worst and most rapidly fatal cases often
show post mortem but very slight lesions,
and cases that from a clinical standpoint
may seem very light often show post mor-
tem extensive pathological changes. Some
of the forms of diarrhea are undoubtedly
infectious. Clinically we see cases with
marked nervous symptoms, high fever, se-
vere diarrhea, and rapid emaciation ending
fatally, and the autopsy reveals very slight
lesions. The conviction is forced on one
that these cases are due to the absorption of toxic substances produced by bacteria, the microorganisms reaching the intestinal tract mainly through the food.

The function of digestion and absorption must not, however, be overlooked, and proper hygienic, dietetic, and medicinal treatment must be combined with suitable antiseptic remedies. It is to be remembered that intestinal digestion is of much greater importance to the baby than stomachic digestion, the digestion of milk being largely accomplished in the small bowel.

The Treatment of Acute Intestinal Indigestion, or, as it is often called, Simple Diarrhea. —Prophylaxis includes what has been said earlier in this article on infant feeding. Overfeeding, improper food, or the quality of the food may be at fault. Children from six to eighteen months of age are especially liable, as weaning, bottle-feeding, and the second summer all fall within this period. All means employed to improve the hygienic conditions of the food are important. Removing the children from damp, poorly ventilated rooms to the open squares, or better to the country or seashore for a few weeks, or a daily visit to one of the free sanitariums now usually found near all large cities, is of distinct advantage. A weakened physical condition is a distinct predisposing cause, the healthy baby being less susceptible to diarrhea than the weaker one.

As by far the greater number of cases of summer diarrhea begin as acute intestinal indigestion, the prompt treatment of this condition becomes a matter of great importance. Undigested and decomposing food is always present in the bowel, and in the acute cases inflammatory changes in the intestinal mucous membrane are not present. Hyperemia and an increased secretion of mucus are usually all that exist. As a rule, to which one occasionally finds marked exceptions, it is found that the longer the disease has existed and the more marked the symptoms, the greater are the pathological findings in the bowel, the lower ileum and colon being the common seat of such inflammatory changes. Absolute rest should be insisted upon; infants, if fretful, may be carried on a hair-pillow; older children should be kept in bed. All soiled diapers should be removed from the room and washed in an antiseptic solution. The child if possible should be removed to good hygienic surroundings, and a tepid bath be given every day. During the warmest hours of the day the child should preferably be kept in a cool, darkened room. In the cooler hours of the morning, afternoon, and evening, keep the baby out-of-doors in the baby coach rather than on the lap. Fresh air is very important for these cases, and the presence of fever is not sufficient cause for keeping the infant indoors. The clothing should be loose, of light flannel or wool—a shirt, diaper, stockings, and long, loose outer garment being all that should be worn. Extra covering may be necessary at night. The room should be large and well ventilated, care being taken to protect the child from draft. During the first twelve or twenty-four hours the digestive organs should be given, if possible, absolute rest; this can only be accomplished by withdrawing food entirely and giving during this period small quantities of sterile water, one to two ounces every hour, to which five or ten drops of brandy may be occasionally added if much depression is present.

Breast-fed infants should be kept from the breast during the first twelve or twenty-four hours, when nursing may be cautiously resumed, the interval between nursings lengthened, and the time allowed for nursing shortened; and later may be given, before nursing or the breast, milk diluted as has been before mentioned. If vomiting is present to any marked degree, milk should, in the case of bottle-fed babies, be entirely withheld for a period of several days or more, and during this time the infant should be given freshly expressed beef juice, mutton broth, or beef broth, or albumen-water made by dissolving the white of one egg in half a pint of sterilized water. When the acute symptoms have largely disappeared, cow’s milk greatly diluted or peptonized may be gradually substituted, and the proper diet according to age be slowly returned to.

In order to clear the bowel of fermenting, decomposing food, a laxative of castor oil two teaspoonfuls, or calomel one to two grains, may be given to a child one year old.

Salol and bismuth should now be administered, from four to six hours being allowed for the laxative to operate. Salol two grains, bismuth subnitrate ten grains, may be given every three hours to a child of one year. Opium may or may not be required; it is always to be given in a separate prescription, and only to be administered for two distinct reasons—to check excess of peristaltic action, and to relieve pain. To an infant of twelve months Dover’s powder one-fourth grain, one-half minim of the deodorized tincture of
opium, or from six to eight drops of paregoric, may be given every two, four, or six hours as occasion demands. Salol and bismuth should be continued some days, the dose being gradually diminished, and the remedies not discontinued entirely until some days after all symptoms of the disease have disappeared.

Chronic Intestinal Indigestion, Chronic Enterocolitis, Chronic Diarrhea.—The prophylaxis includes all that has been previously mentioned on infant feeding, hygiene, fresh air, etc. Summer heat and a weakened constitutional condition are powerful predisposing causes. We have in this disease food in the intestine undergoing fermentation, causing continued irritation of the intestinal mucous membrane and resulting in inflammation, and not uncommonly in ulceration. The microorganisms present and the bacteria introduced with the food are factors tending to increase the inflammation already present in the lower ileum and colon. The prophylaxis of this disease therefore embraces the prompt treatment of acute intestinal indigestion and all acute inflammations of the intestinal tract, the prognosis being more unfavorable and the intestinal lesions more serious in proportion to the acuteness, severity, and frequency of the gastrointestinal symptoms that antedate the chronic condition. The treatment by diet follows the rules laid down for acute intestinal indigestion. Beef juice or animal broths may often with advantage be continued for some days, as their small bulk and slight residue in the bowel have little tendency to promote peristalsis or keep up fermentation.

Stimulants are usually required, ten to twenty drops of whiskey every two or three hours being generally sufficient. Opium does not occupy the same prominent position as in acute indigestion; it is especially useful in the acute exacerbations to relieve pain and check excess of peristalsis. It is to be given in a separate prescription and in the same doses as in acute intestinal indigestion. An occasional laxative is of advantage, as castor oil or calomel. Bismuth subnitrate ten grains, salol two grains, given for long periods, have in my hands proved the most successful drugs. Large doses of bismuth must be given to accomplish the desired result. Bismuth salicylate, five grains, is also in this disease a valuable drug.

Irrigation of the large bowel, carefully and thoroughly carried out each day with a fountain syringe and No. 12 catheter (not too flexible) is of decided benefit. A gallon of fluid should be employed for each irrigation, the liquid being at 98° to 100° F. Saline solution, boric acid solution, or nitrate of silver, 7½ grains to the gallon, have all in my hands been most useful. The child lies with the hips elevated; the catheter, well oiled, is allowed to gently pass six or eight inches up the bowel, the liquid being allowed to flow gently during its introduction, and the reservoir not raised more than three feet above the child's body.

In the more severe cases of chronic intestinal indigestion marked catarrhal or follicular inflammation of the lower ileum and upper colon is usually present, and follicular ulceration is not uncommon. Astringent emenata in these cases often do much good—i.e., the saline or borax irrigation may be followed by six or eight ounces of water containing three drachms of bismuth subnitrate. Absolute control of the child's diet is essential to success, and the best hygiene, with plenty of fresh country or seashore air, is of importance.

Acute Ileocolitis, Summer Diarrhea.—This is the disease to which hundreds of children fall victims each summer. It is largely a disease of hot weather, and is rarely seen in cool weather except under bad hygienic surroundings. The lower part of the ileum is the seat of distinct inflammation, the most marked lesions being in the neighborhood of the ileocecal valve. These lesions are largely due to the microorganisms present. Prophylaxis includes all that has been said previously in connection with diet, hygiene, bathing, clothing, etc., and the prompt treatment of every diarrhea, no matter how mild the attack. Milk is forbidden during the first few days, and beef juice or animal broths may be allowed during this period; preferably, however, nothing but sterile water with small doses of whiskey should be administered during the first twenty-four hours. In bottle-fed babies the prompt securing of a wet-nurse may be the only means of saving life. All soiled diapers should be washed in an antiseptic solution. The initial laxative is of advantage unless contraindicated by the child's extreme prostration.

Calomel in small doses, ½ grain every two hours, especially if much nausea and vomiting are present, and given early in the disease, is one of our best remedies. It is rarely necessary to continue its use more than twenty-four to thirty-six hours at one time. Opium will be required in almost every case;
it is to be given according to the rules laid down earlier in this article. It should never be given in sufficient quantity to entirely check peristalsis. Hot flaxseed poultices applied to the abdomen for twenty-four hours, or a spice plaster kept in position long enough to well redden the skin, are helpful in relieving pain and checking vomiting.

Bismuth subnitrate is capable of doing much good; large doses must be given—two drachms to the usual twenty-four-hour amount required for a child twelve months old. Salol, two grains, may with advantage be combined with each dose of bismuth given. Bismuth salicylate five grains, bezonaphthol one grain, and naphthalin given in two-grain doses, have been used with benefit. Stimulants will be required in every case. The best antiseptic results are obtained by the external application of cold in the form of bathing or sponging.

The use of local treatment by means of irrigations is in this disease an absolute necessity; many cases are undoubtedly lost through a failure to appreciate their usefulness. The amount of liquid used—saline solution, boric acid solution, or nitrate of silver solution—must be large (a gallon), and the irrigations must be repeated daily. Emetics of ice-water, a pint repeated every few hours, are also of great benefit.

THE OPERATIVE TREATMENT OF WELL ADVANCED CARCINOMA OF THE UTERUS.

VJEIT (Berliner Klinische Wochenschrift, No. 15, 1899), though placing little credence in the majority of published statistics, holds that certain of them offer conclusive evidence as to the number of permanent cures accomplished by radical operation in cases of uterine cancer. Among these he ranks Krukenberg's publication, in which it is stated that out of 149 collected cases operated on five years or more before the report, thirty-six were free of recurrence. Fraenkel states that 82 out of 230 cases were permanently cured. Hence it is perfectly evident that the disease must be ranked with those which offer a good prospect for entire removal. Krukenberg, however, personally told the author that he could note in his own service not more than eight per cent of cases free of recurrence for five years or more.

As a means of increasing the percentage of radical cures an early diagnosis, an operative technique which avoids the danger of infection, and an extensive operation are necessary.

A timely diagnosis is an element of the first importance in assuring a permanent cure. A canceroid of the vaginal portion occurs in early life, and malignant disease of the uterine body after the menopause. An early diagnosis of both these forms is not difficult, the former being characterized by bleeding on slight mechanical disturbance; the latter by a spontaneous bleeding after the menopause. Scrapings examined with the microscope usually give positive evidence. Cancerous nodules in the cervix, or infiltration of the cervical mucous membrane, are more difficult of detection; the latter causes a catarrhal discharge, the former simply pain in the sacrum, pressure, and similar vague symptoms. Bleeding does not occur early. Swelling of the cervix, particularly behind the external os, thickening and increased density, together with a certain patulousness of the os to the examining finger, combined with excision of a portion of the apparently diseased tissues for microscopical examination, may aid in making a diagnosis.

As to the question of operation when the disease has extended beyond the uterus, in the vast majority of cases this is hopeless, since a complete removal is impossible. The operation required is, moreover, so extensive that many patients will necessarily perish as an immediate consequence. The removal of the iliac and vertebral glands should always be practiced when these can be felt. At the best, operations upon these cases of widespread disease can save only an occasional one; hence the main hope of better statistics in operation for cancer lies in a more general, cultivated diagnostic skill.

RESECTION OF THE GREATER PART OF THE STOMACH FOR CANCER.

LANDOUZ (Journal des Praticiens, No. 11, 1899) reports the case of a woman, forty-one years old, who suffered for several months from a cancer of the pyloric region of the stomach. It was not ulcerating, but was easily accessible to palpation; it was the cause of incessant vomiting and rapid emaciation. The entire diseased area was resected, together with some neighboring involved ganglia. About three-fifths of the stomach was removed, and the remainder was connected with the jejunum. The patient recovered and was well four months later.
THE EMPLOYMENT OF QUININE IN MALARIA.

If there is one therapeutic procedure more certainly fixed in the minds of modern clinicians than another, it is the employment of quinine as a specific in the treatment of malarial infection; and while we know that certain forms of the disease are conquered with greater difficulty than others by the use of this drug, the fact remains, as has been proved by indubitable clinical and experimental research, that quinine is facile princeps the remedy.

It seemed somewhat startling therefore when it was announced that Dock, of Ann Arbor, Michigan, proposed reading a paper, with the title similar to that heading this editorial, before the Section of Practice of Medicine of the American Medical Association, for it seemed that such a title indicated that we were not confident of the correctness of this method of treatment; but those who heard Dock’s paper soon learned that there was no intention of doubting its usefulness, but that his endeavor was to indicate the proper employment of the drug in more minute detail than is commonly accorded it. In this respect we think he did a distinct service, for there can be no doubt that in many instances excessively large doses of quinine are administered. To be sure, certain types of fever require large doses, but on the other hand we fear that too often large doses are given of which only a part is immediately absorbed and only a part combats the malarial organism, while the greater portion is absorbed too late to be of any benefit, and may be not only useless but harmful.

It has been pointed out by some clinicians that in their opinion the best time to administer quinine is immediately after the paroxysm, as under these circumstances it acts as a distinct prophylactic in regard to subsequent attacks; and by others that it should be given four or five hours before an expected paroxysm, so that it may be absorbed and exercise its effect upon the malarial organism early enough to prevent the characteristic changes which are followed by such disastrous results to the patient.

It seems to us that neither one of these rules can be universally adhered to, and that the administration of the drug several hours before an expected attack is the correct method to employ in those patients which have widely separated attacks, every second or third day for example, whereas in the
LEADING ARTICLES.

quotidian type, or in any infection by the estivo-astrumal parasite, where in many cases fever of the remittent rather than the intermittent variety occurs, the administra-
tion of the drug during the period of decline is probably the more correct method.

In the discussion of Dr. Dock's paper it seemed to be universally agreed that a mercur-
ial, or other hepatic stimulant, should precede the quinine. In regard to malarial hematuria,
the conclusion seemed to be that in a certain number of cases, exactly what class it is diffi-
cult to determine, quinine is capable of doing harm, while in others it is capable of doing
distinct good. The probable solution of this vexed question as to the administration of
quinine in blackwater fever lies in the ability of physicians to make examinations of the
blood for the malarial parasite. If the mala-
rial parasite is present, the damage which it is capable of doing, aside from any condition of the
urine, is sufficiently grave to justify the physician in administering quinine; but if, on the other hand, the malarial parasite is
not found in the blood and the bloody urine is but a manifestation of malarial cachexia,
associated perhaps with a chill due to other causes, then quinine has no indications for its
use and is probably capable of doing harm.

An interesting question also arises in re-
gard to the value of quinine when given hypodermically. It was suggested by one or
two speakers that it be used in this way in those cases in which large doses are inadvi-
sable and in which the condition of the stom-
ach was such that quinine could not well be
given, either because it would not be absorbed
or because there is vomiting; but the editor of
this journal suggested that one of the
reasons why hypodermic injections of quinine
were not satisfactory was that the drug was
precipitated by the alkaline juices of the tis-
sues, unless it was given in an acid solution,
and being precipitated was so slowly absorbed
that it really produced no effect upon the
attack for which it was administered. It was
also suggested by the writer that in urgent
cases of malarial infection, when the parasite is
found in the blood, the drug should be
used according to Bacelli's method. In other
words, the hydrochlorate of quinine should
be dissolved in normal saline solution and
injected intravenously into one of the veins of
the lower extremities, as by this means any depressing effect which might be exer-
cised by the quinine upon the heart would be avoided and instantaneous action upon the
parasite would be accomplished. Of course,
this method is not to be employed except in
very urgent cases, nor is the hypodermic
method to be used, since it is apt to be futile
and produce much subcutaneous irritation.

Discussing these remarks, Dr. J. C. Wilson
expressed his belief that the hypodermic use of
quinine was advisable, but the further progress of the debate did not show that the
others present agreed with him; indeed, on
the contrary, hypodermic medication of quin-
ine in malarial fever was not received with
general approval.

THE TREATMENT OF ADVANCED TU-
BERCULOSIS.

There are few conditions which appeal to
the sympathies of the physician more strongly
than does advanced pulmonary tuberculosis,
and there are few in which he is so powerless
to do the patient much good. There comes a
time, however, in the treatment of such a
patient when it is the duty of the physician,
who is utterly unable to restrain the progress
of the disease, to do those things which will
render the remaining days of life most com-
fortable and satisfactory to the patient and
his friends, and undoubtedly in this late and
hopeless period of the disease much can be
done to relieve suffering and discomfort.

It is not our intention in this editorial to
deal with all the measures which can be used
under these circumstances. Personally we
believe that an active normal liquid, or tinc-
ture, of cannabis indica, properly used, will
very frequently, by benumbing disagreeable
sensations and checking cough and improving
the appetite, do the patient a great amount
of good. The sweats, if they are profuse,
can also be controlled by camphoric acid, and
diarrhea relieved by pleasant astrigent mix-
tures, while neuralgic pains can be relieved
by a local application of menthol and similar
substances.

A method which has found some popularity
in France is the use of the combination of
Hoffman's anodyne, extract of opium, and a
syrup. Thus Castel prescribes the following
mixture, all of which may be taken in twenty-
four hours:

Hoffman's anodyne, 6 drachms;
Fluid extract of opium, 5 minims;
Syrup of lettuce, 4 ounces.

One or two teaspoonfuls or more of this may
be taken from four to eight times in the
twenty-four hours with advantage.

This method of treatment has no particular
disadvantage save perhaps that it might tend
to produce constipation, which is a disadvan-
tage in those who are not suffering from
diarrhea; but it is claimed that it also tends
to check night sweats, that it increases the
appetite, diminishes the cough and ecec-
storiation, relieves the dyspnea, and actually
increases the weight. Nor is the effect solely
to relieve and benumb; by its influence over
tissue waste it probably actually aids the pa-
tient in maintaining his strength.

There is only one suggestion which we
have to add to this, namely, that in those
cases where the opium seems to produce
nausea the following day it may be wise to
employ morphine in place of the opium, and
when the morphine seems to produce dis-
agreeable after-effects to add to the mixture
a small dose, say \( \frac{1}{16} \) of a grain, of nitro-
glycerin, which in many cases may prevent
the disagreeable after-effects of the opiate.

\[ A \text{ NOTE IN REGARD TO THE TREAT-
MENT OF OBESITY.} \]

Not long since we were wont to regard
obesity as dependent upon some unknown
perverted physiological factor which was
supposed to be practically identical in each
case, but advances which have been made in
the study of metabolism and in the influence
of thyroid gland upon nutrition have proved
that obesity may be due to many different
causes, in some of which the use of thyroid
gland, by correcting disordered metabolism,
may give relief, while in others it fails to be
of very material advantage.

An important point to be remembered in
the administration of thyroid gland in the
treatment of obesity is that this substance
not only causes a great loss of hydrocarbons,
but also that it very distinctly increases
tissue waste in the nitrogenous substances
of the body, and therefore, while it is being
given to cases of obesity, their diet should be
ample in the way of meats and similar nutri-
tious food.

Exercise in many of these cases of obesity
must be regulated with the greatest care,
since often the heart power, while the thy-
roid gland is being taken, is not sufficiently
strong to stand the severe exercise to which
obese persons often subject themselves, with
the false idea that it is the proper thing to
do. Walking must be regular and moderate,
and should be frequent rather than pro-
longed to the point of severe fatigue. Mas-
sage is often exceedingly valuable in these
cases, as it aids in the circulation of the
blood and tends to keep moving a large
amount of the juices of the body. In some
instances, probably those in which the thy-
roid will do the most good, the obesity seems
to be distinctly a hereditary condition.

An interesting paper in reference to this
fact has recently appeared in \textit{La Presse
Médicale} of May 24, 1899, by Chauffard.
In this article he gives the genealogical tree
of a family which suffered from hereditary
obesity, and still another which suffered from
obesity, gout, and diabetes; in other words,
the family was one in which there was a per-
version of the normal metabolic processes.

In one case, of a young man of thirty-four
years suffering from hereditary obesity, death
occurred from cardiac failure.

\[ THE \text{ NECESSITY OF USING CAUTION IN 
PRESCRIBING CLIMATE AS A 
REMEDIAL AGENT.} \]

In the midst of a large amount of study which
has to be carried out by the modern medical
student, it is very difficult to give him defi-
nite and clear ideas about remedial measures
other than drugs, and there are few schools
in the country which teach students the dom-
inant facts in regard to climatology, balne-
ology, and similar useful remedial processes.
As a result of this lack of knowledge, many
physicians are wofully ignorant and are unable
to give their patients competent advice in
regard to the climate which they should seek
for the benefit of their health.

There are two classes of patients to which
the question of climate is most important and
in which bad advice is not only followed by
no benefit but is fraught with danger, namely,
patients suffering from pulmonary tubercu-
losis and others from renal disease. Physi-
cians of experience who are in the habit of
referring patients to climatic resorts are well
aware of the fact that a moderately high
altitude, dryness of the air, stillness and free-
dom from dust, with many hours of sunshine,
are absolute necessities for the best results
which are to be obtained, and that for renal
cases a gentle balmy climate, with moderate
temperature which is as near as possible con-
stant, is an essential feature.

Too frequently physicians hold out vain
hopes to patients in regard to what climate
can do for them, and actually do not recog-
nize the fact that after pulmonary and renal
disease has advanced to a certain stage death
is inevitable, and that very soon. Under
these circumstances patients are advised or
permitted to leave their homes and make an endeavor to regain that health which is impossible, only to die from exhaustion on the journey or soon after arrival, and by reason of their large expenditures to leave those who are dependent upon them even more poverty-stricken than before.

We are glad to notice that the Denver Medical Times has in its May issue an editorial entitled "Patients Not Fit for Climatic Treatment in Colorado," in which the writer calls attention to the fact that many unfit patients are sent to that State who are so far gone that they die in the hospitals within three weeks after arrival, and a vivid description is given of how frequently the poor patient goes to Colorado with emaciated form, cyanotic lips, flushed cheeks, graveyard cough, and too often exhausted exchequer. He is unable to sleep in a recumbent position, develops edema of the feet, and unable to return alive, dies far from home in lonely misery.

As this editorial writer well says, if such patients are to go to Colorado, let them go if possible within a few weeks of the beginning of the cough, and if they cannot be sent before excessive destruction of the lung occurs, be merciful enough to let them remain at home surrounded by friends and home comforts during their last hours, that they may at least die in peace.

THE TREATMENT OF PULSATING EXOPHTHALMUS BY LIGATION OF THE CAROTID ARTERIES.

A pulsating exophthalmus, secondary to traumatism, is nearly always due to an injury of the internal carotid artery and cavernous sinus, mechanically so placed that the arterial blood passes directly into the lumen of the sinus. The increased blood-pressure resulting from this causes venous stasis.

Boden (Deutsche Zeitschrift f. Chirurgie, May, 1899) states that the symptoms of this injury develop in a shorter or longer time, depending upon whether the wound of the carotid is a small or a large one. Swelling of the eyelids, possibly such marked serous infiltration that the functions of the eye muscles are abolished, chemosis, and marked venous dilatation, are noted. The papilla becomes edematous, the retinal vessels are dilated, retinal bleeding is frequent, and the entire eyeball is pressed forward. The superior ophthalmic vein becomes dilated, incident to the increased pressure, and its walls are thicker. The pulsation of the eyeball can be both seen and felt. This venous dilatation may extend upward over the forehead. A bruit, continuous, with pulsatile exacerbations and often loud and distinct, can be heard, and the patient commonly complains of a beating headache, and failure of vision. The lesion is often bilateral.

As to treatment, the patient should be kept to bed and kept under the influence of narcotics, when the communication between the artery and vein is very small. Under such circumstances the opening may close under the "rest treatment."

Compression of the common carotid artery is a means of treatment which naturally suggests itself. The artery is accessible, and by firm pressure upon it a condition of blood stasis is encouraged which favors the formation of an occluding clot. Instrumental pressure is, however, practically impossible, while digital pressure has proven inefficient and extremely painful.

The oldest treatment still remains the best—that is, the ligature of the common carotid of the affected side. In a case reported by Boden, this operation was followed by immediate relief of the unbearable headache, by return to normal vision, and by recovery from all symptoms. It often occurs that ligation of the artery of one side is not efficient. A collateral circulation in the case of unilateral ligation is supplied by the vertebral arteries, by the carotid of the other side, and by the anastomosis between the superior and inferior thyroids. If this collateral circulation develops too quickly, insufficient time for the organization of the thrombus is allowed, and symptoms recur, in which case ligation of the carotid of the other side is indicated.

Of fifty-two collected cases of unilateral ligation of the common carotid artery for pulsating exophthalmus, twenty-six were cured, twenty were improved, six were not improved—that is, eighty per cent were either cured or improved. In six of the cases, because the operation was undertaken too late, the sight of the eye was not restored.

Concerning the mortality of the operation—ten per cent—this is distinctly high. Three cases perished of sepsis, two of hemorrhage, and in one the cause of death was undiscovered. Thus, in five out of the six fatal cases, death could have been averted by a more careful and modern technique.

Both common carotids have been ligated for pulsating exophthalmus six times. In
the first case an interval of fourteen months elapsed between the two ligations. The vision of the eye was lost. In the second case an interval of a month elapsed between the two ligations. Four weeks later the patient was entirely well, and the power of vision was markedly increased. In the third case an interval of about two months elapsed between the two ligations. The cure was a complete one. In the fourth case the result was uncertain. In the fifth case an interval of sixty days elapsed between the two operations. The patient gradually improved, and after a year was almost well.

The sixth case is reported by Boden. The patient had received a blow on the skull, and four months later presented himself with the characteristic symptoms affecting the right eye. The right carotid was ligated under Schleich's anesthesia and divided between ligatures. A month later, after five days' digital pressure, the left common carotid was ligated. There was no immediate relief from pain, and though the pulsation was diminished, it was still persistent. The bruit could be made to disappear by pressing on the left external carotid, the left superior thyroid, or the right external carotid. The head pains got better after a time, but recurred with almost their original violence. A mass of blood-vessels, the size of a hazelnut, placed on the orbital margin and pulsating markedly, if pressed upon, caused a cessation in both the headache and the bruit. Guided by this fact Dollinger made an incision along the upper orbital border, and after ligation of a number of smaller veins, exposed the superior orbital vein (which was as large as a lead-pencil) and placed a thread about it. Thereafter all subjective symptoms ceased.

In case bilateral carotid ligation fails to cure the pain, bruit, and pulsation of the arteriovenous aneurism, there is still left a complete cleaning out of the orbital contents, a procedure less severe than it at first seems, if it be recalled that vision is commonly destroyed by the disease when unchecked.

THE DIAGNOSTIC VALUE OF RENAL PERMEABILITY TO METHYL BLUE IN SURGICAL AFFECTIONS OF THE KIDNEY.

Since the chemical and physiological examination of the urine determines simply the ingredients of this fluid and their toxicity, throwing only an indirect light upon the question as to the amount of toxic substance retained in the blood, incident to imperfect functioning of the kidney, any method that will enlighten us as to the eliminating power of this organ must necessarily be extremely valuable, not only to the physician but to the surgeon, whose judgment as to the advisability of operation must often depend largely upon the dependence he can place in the depurative action of the kidneys. An attempt has been made to determine what has been called the permeability of the kidneys, by examining the urine for various substances easy of chemical recognition, which when taken into the system are eliminated by the kidneys.

Undoubtedly the best of these means of investigation is that proposed by Achard and Castaigne, who in 1897 endeavored, by the injection of methyl blue into the subcutaneous cellular tissues and subsequent urinary examination, to determine the renal permeability. They found that in nephritis the elimination was retarded.

This observation was corroborated by others, but Bard observed that while this retardation was observable in some cases of nephritis, in others the appearance of the blue in the urine was precocious. It was also noted that the methyl blue was sometimes eliminated in the form of a leuko-derivative, called chromogene.

Chaufard called attention to the fact that the elimination sometimes appeared in the form of a continuous cycle—that is, there was a regular increase in the quantity observed until the maximum was reached, then a regular diminution. At other times elimination was continuous but polycyclic—that is, the blue was passed irregularly, sometimes in large quantities, sometimes in small quantities; finally it might be passed intermittently, the urine in the intervals containing none of the coloring matter. Achard and Castaigne note that the prolongation of the elimination is a sign of renal impermeability.

Albarran and Bernard (Annales des Maladies des Organes Génito-Urinar'es, No. 4, 1899), noting that few authors have systematically studied the results to be obtained by this method in surgical affections, have carefully investigated five cases of pyonephrosis, two of hydronephrosis, two of renal tuberculosis, two of renal neoplasms, three of single kidneys left after ablation of the organs of the opposite side, nine cases of pyelonephritis, and one case of reflex polyuria.
The method of procedure was as follows: Fifteen minims of a five-per-cent solution of methyl blue was injected deep into the thigh or loin, the bladder having previously been emptied. Thirty minutes after injection the urine was collected in a glass, and this collection was repeated every half-hour until blue coloration was noted, from which period the collection was made every two hours until the elimination ceased. The blue was extracted by means of chloroform, after which the remaining liquid was examined for chromogene. Careful chemical examination of the urine was also made at the same time. In all cases of unilateral lesions the ureters were catheterized, and the urine from each kidney taken separately. The cases are reported in full with ingenious charts.

As a result of this study, Albarran and Bernard note that renal permeability is not a physiological entity, but that the kidney exerts an elective action, each substance possessing its own coefficient of elimination. The various substances used in experimental work have not always shown a concordant elimination. The methyl blue method is, within limits, capable of suggesting the existence of marked disturbances of the renal function; but the findings of this method in themselves are not safe indices as to either the nature or the degree of the renal lesions.

The most important factor in the elimination of methyl blue is its intensity. A permeable kidney lets coloring matter pass in large quantity; an impermeable kidney lets it pass in small quantity. This is the most reliable and important indication given by the method.

The delay in the appearance of the color is not to be trusted as a sign of kidney involvement. The elimination is commonly slow in a crippled kidney, but not always so.

The time during which elimination continues has some relation to the existence of compensating hypertrophy, either anatomical or histological. Thus there is a prolonged period of elimination in interstitial nephritis.

The progress of the elimination does not seem to give any clear indications. In pyelonephritis the elimination may take place in the form of chromogene, or it may be of methyl blue and chromogene disassociated, or these two elements may be eliminated together. This form of elimination suggests neither the nature nor the degree of the renal lesions, it simply indicates the existence of kidney complications.

In blocked kidney the elimination is delayed, lasts but a short time, and is very moderate in quantity. These departures from normal are proportionate to the kidney lesions.

In caseating renal tuberculosis the kidney may be perfectly impermeable to the blue. In such affections the kidney of the opposite side exhibits a precocious, prolonged, and abundant elimination. Renal neoplasms seem to have no effect on elimination.

The authors insist upon the importance of ureteral catheterization in all these studies, and hold that for the diagnosis and prognosis of unilateral surgical affections of the kidneys the method of Achard is of distinct service, but only when it is associated with ureteral catheterization.

This communication is of very great value. The study has been so carefully conducted that it can be open only to the criticism that the conclusions are drawn from a somewhat limited number of cases. While disposing of the exaggerated claims at one time made for this method of diagnosis, it shows that it is by no means worthless; and in spite of recent papers upon the uselessness of the methyl blue injections as aids in the diagnosis of kidney affection, the conclusions of Albarran and Bernard are likely to be received as authoritative. They are unfortunately based upon a technique which is practicable to very few of our practitioners.

---

**Reports on Therapeutic Progress**

**Disinfection of the Mouth.**

The Scottish Medical Journal for April, 1899, has in it a paper on this subject by Maylard. He says his object in writing this paper is to try and prove that the upper part of the alimentary canal, and more particularly the mouth and fauces, may prove a very ready receptacle for noxious material, which may subsequently find its way into the system. The facility with which septic or pathogenic substances will gain an entrance into the lymphatic channels will no doubt be very largely influenced by the condition of the lining mucous membrane; in other words, decayed teeth, ulcers, fissures, abrasions, or inflamed surfaces will very materially help to let infective material into the lymphatics.

If further reasons were required to support the belief that the mouth and fauces play an important rôle in certain diseases, it would be found in the usually accepted opinion that
diphtheria, scarlet fever, and quinsy have their initial symptoms in affections of the fauces. Dr. Maylard says he might add, for whatever value may be attached to it in this connection, a story which he recently heard told of a medical officer of health of one of the great provincial cities. He had been asked by two medical men to see a case which they strongly suspected was one of typhus. The medical officer verified the diagnosis without any doubt, and on leaving the patient commenced to spit, stating at the same time that it was his custom to continue to do so for the space of an hour after being in the presence of such a class of cases. This respected officer, whose peculiar and special function it was to prevent the spread of infection, and to adopt all such measures as should conduce to the welfare of the community whose general health formed his special department, evidently forgot that in ridding himself of the infective material, which he conceived it possible might get into his mouth, he was employing a method most conducive to the spread of the disease. Perhaps the simple precautionary measures to be presently described might suggest a better means of protecting the individual, while it would not endanger the community.

If, then, as there seems very little doubt, certain recognized specific conditions owe their origin to infection conveyed by or through the lining walls of the upper alimentary tract, may we not with some just reason conclude that even other diseases, the true source of which we cannot trace, may have their origin in the same way? Certainly there is no part of the whole body where infectious material, whether it be microbial or otherwise, can find such advantageous collecting and resting-places as is afforded by the many dental crevices or mucous membrane folds of the mouth and fauces; where, too, microorganisms can develop and multiply almost unimpeded. Unlike the stomach and intestines, where there is the gastric juice and the bile, the mouth possesses no similar secretion capable of neutralizing or inhibiting the effects of noxious material, for the saliva has probably no influence in this direction. That decaying teeth may prove a source of infection is probable, but they cannot be a very fertile source, when it is considered how many people have bad teeth, and what a comparatively few have enlargement of the cervical glands or other manifestations of disease. The probable reason of this exemption, no doubt, is that the cavity of a decayed tooth is such a hotbed of stinking saprophytic microbes that it proves more than the refined and sensitive cocci and bacilli of disease can stand. No tubercular bacilli could certainly thrive in such a soil, and that is probably the reason that the mouth is so remarkably free from local manifestations of tuberculosis, when, through the ingestion of uncooked milk and infected meats, so many opportunities are afforded for its being so.

If the above remarks have any cogency, they certainly point to the need of adopting some measures which will lessen, the possibility of infection by the mouth. It may seem like descending to a very low and homely standard of precaution to touch upon such simple personal matters as the daily cleansing of the teeth with a brush. But there is a great deal more involved in that simple process than the mere supposed endeavor to keep the teeth white on their anterior or labial surface. The efficient scrubbing with a brush cleans out many of the little holes and corners in and between the teeth where infective material can lodge. The process of freely rinsing the mouth also serves to mechanically dislodge stagnant material in other parts. He would therefore not think lightly of this simple daily practice, which, however frequently adopted, should never be omitted at night. But he says he need hardly point out that by disinfection of the mouth he means a good deal more than this. When from any cause there is some lesion of the lining membrane of the mouth, either of the nature of a traumatic abrasion, an ulcer, an inflamed mucous surface, or a decayed tooth, the mouth should be freely rinsed with some antiseptic solution. He knows of none better than a weak solution of Condy’s fluid; it is not distasteful, and a strong solution of it can be kept ready for dilution to the required strength. Doubtless those possessing sound and healthy constitutions, and not exposed to sources of infection, need but little to take protective precautions; but where the opposite conditions exist, he does not think too great care can be exercised. Wherever there is a known tubercular predisposition there should be certainly the utmost care taken both to cleanse and disinfect the mouth. When also there is exposure to certain infective diseases, more particularly to those of diphtheria, scarlet fever, and possibly typhus, the mouth should certainly be well disinfected after exposure to infection.

There is yet a somewhat different class of
cases, which manifests unmistakable evidence that the mouth is capable of supplying infectious material to distant parts. The author has frequently noticed—or, rather, he at one time did, for now he takes precautions to avoid it—that after exercising cervical glands under the strictest antiseptic precautions, and where previous to operation there had been no broken skin or sinus leading from the glands to the skin surface, infection of the wound took place if he attempted to completely close it. It was not the result of tension, but, he believes, the infection of the wound through the divided afferent lymphatics, which still were capable of conveying septic material from the mouth. To prevent this a portion of the wound should be stuffed with sterilized gauze, the remaining part being stitched, if deemed advisable. The mouth should be frequently rinsed with weak Condy's fluid, and always after food. How potent the cleansing properties of this fluid are he has frequently seen illustrated in cases where operations have been performed upon the mouth—such, for example, as excision of the tongue or parts of the jaw, where by its frequent and free use inflammation is checked and the parts kept, as we say, perfectly sweet.

ON THE PREVENTION OF VALVULAR DISEASE OF THE HEART.

The Edinburgh Medical Journal for April, 1899, contains an article by Caton upon this most important theme. He thinks that at the present time most members of our profession regard such effort as this as a hopeless task. In the spirit of the fatalist Moslem, they believe that if heart complication comes, it comes; it may possibly subside, though usually it does not, and they conceive themselves powerless to influence it. This, Dr. Caton says, was his belief and practice during the first dozen years of his professional career, but eighteen subsequent years of observation, directed especially to this question, have securely founded the conviction that much may be done to prevent and to arrest rheumatic endocarditis. So clearly has the good to be done become evident in his eyes, that he should now feel it a distinctly immoral action on his own part to omit certain precautions and certain methods of treatment.

1. As Regards Methods of Prevention.—Rheumatism, when once existing, seems to be aggravated by exposure to cold, and by checking (through chills) the profuse perspiration incident to the ailment; this is probably the opinion of most physicians. Caton keeps in his wards a stock of warm flannel garments expressly for the use of these cases. Every patient is clothed from head to foot in warm flannel (with sufficient changes of the same) during the whole of the acute period. He is kept in the most absolute rest in bed. He is usually treated with gentle chologogues and with one of the ordinary salicylate preparations; the diet is a light and simple one, excluding for a considerable time all red meat. The heart is examined daily. If the pain fails to yield in any joint it is quickly dispelled by the use of one or two small blisters applied locally, and followed by poultices.

Any one who has tried Dr. Herbert Davies' method of treating rheumatism by small blisters to the joints knows how effective that treatment is.

Usually without this adjuvant, however, the pain and fever speedily subside, but to prevent relapse and endocardial trouble, Dr. Caton always maintains the remaining treatment, with the exception perhaps of slacking off the salicylate. The prolonged rest, warmth, and quiet seem to him very important as means for preventing mischief, for cardiac trouble not infrequently tends to come on late—even after all pyrexia is over. Under this treatment eighty-two or eighty-three per cent of his cases get well without any cardiac trouble at all. The remaining seventeen or eighteen per cent who are attacked form, he thinks, a low average.

2. Efforts to Arrest Cardiac Valvular Mischief when it has Begun.—If endocarditis shows itself by the development of an apex bruit, and by accentuation of the second sound at the pulmonary valve, or more rarely by a bruit at the aorta, the author adopts the measure which is found effective for a refractory joint, namely, the application of small blisters, along with other means. To all appearance the salicylates have little or no beneficial effect on cardiac rheumatism.

The reader may probably ask the question: Is there evidence that stimulation of the surface skin can in any way influence organs lying in the body cavity? All will agree that there can be no direct influence. If there is any effect at all it must be by a reflection through the spinal or sympathetic ganglia, via intercostal and visceral nerves. Is it possible that counter-irritation through these channels can do for the heart what it undoubtedly does for the joints? In reply Dr. Caton says
he can only give proof that certain nerve impulses do travel round by this route. Laborious laboratory experiments gave distinct evidence that stimulation of the thoracic integument produced certain changes in the viscera beneath. Space will not allow him to state details, but he says, in a paper read before the Physiological Society at Oxford, he showed that stimulation, either thermal, electrical, mechanical, or chemical, of the thoracic skin produced changes in the caliber of the arterioles of the lung, also that similar stimulation modified the electrical potential of the intestinal wall, as shown by the galvanometer. These experiments did not prove any therapeutic influence—it would scarcely be possible to prove that by such a method—but they prove that an influence was transmitted round by the nerve communications extending between the surface skin and the organs within. By analogy it may fairly be assumed that likewise a trophic effect, a stimulation of nutritive processes, may be expected to follow such stimulation in an organ whose nutrition was perverted. Familiar examples of such an action might be quoted—e.g., what obstetrician does not know the effect of a sudden dash of cold water on the thoracic skin of a new-born child in quickening respiration? In a faint, is not a like application of avail in stimulating the heart?

The treatment Dr. Caton is advocating is in part founded upon this theory. As soon as a bruit is perceptible—in fact, as soon even as what the French call assourdissement, the muffling of the first sound at the apex, occurs, which is the usual precursor of the bruit—he applies in the course of the third, fourth, fifth, or sixth intercostal nerve small blisters not much larger than a shilling, in succession, one at a time. They give little pain or inconvenience. The patient is kept in bed, absolutely recumbent and as quiet as possible, for several weeks. It is important in his judgment to keep the heart’s action as quiet as possible. Moreover, he gives in addition to the salicylates eight- or ten-grain doses of sodium or potassium iodide thrice daily. This is given in the hope that it may help to absorb inflammatory products.

ON THE VALUE OF MILK WHEY IN INFANT FEEDING.

ASHBY writes on this topic in the Edinburgh Medical Journal for April, 1899.

Whey has been used, time out of mind, as a substitute for whole milk for the infant, when digestion was at a low ebb. It must early have been recognized that cow’s milk curdled in the stomach into masses of sour-smelling curd, upon which the digestive juices were apt to spend themselves in vain, and these were either ejected by vomiting or passed in the feces. Under these circumstances whey was a useful temporary resort, the vomiting or diarrhea ceased, and the digestive powers might be coaxed back into their normal condition.

Dr. Ashby is inclined to think that, at the present time, the value of whey for infant feeding is often overlooked or forgotten, a result no doubt due to the fact that so many tinned or bottled infants’ foods—of the “perfect substitute for mother’s milk” sort—are extensively advertised by their makers, and our more homely milk modifications have been thrown into the shade. But surely no sane individual can ever claim that milk which has been dried, “tinned,” and stocked, can ever again be made to yield a fluid that can compare with fresh milk or milk whey as a food.

Some years ago Frankland suggested whey as a diluent for milk, and gave directions for the preparation of “humanized” milk—i.e., a mixture which resembles woman’s milk in the percentage of its constituents—by mixing together certain proportions of cream and whey. Since then “humanized” milk has been manufactured on a large scale by mixing cream, milk, and sugar-water in various proportions, sterilizing, and sending out in bottles. Dr. Ashby doubts very much if the manufactured article, which is mostly overheated to make it keep good for months, is as good a food as can be made at home by mixing cream, or milk and whey, and using it fresh. There are comparatively few of us within easy reach of a Walker-Gordon laboratory, where we can have any formula for a milk food made up and delivered daily with an exactness we cannot imitate in the household; but we have to depend upon home-made modifications. The temptation, no doubt, is great to fall back upon a manufactured food; it is so much easier to take a spoonful of powder out of a bottle or tin and stir it up with warm water, when the infant has to be fed, than to set aside milk to cream and to prepare the whey. But it is worth all the trouble and time expended on its preparation.

When “rennin” or essence of rennet is added to warm milk, the proteid in the milk—namely, caseinogen—is split up into insoluble proteid casein and “whey proteid,” the latter being unaltered either by “rennin”
or heat. The casein is precipitated in company with the fat, leaving the whey protein, lactalbumin, lactose, and salts in solution. When whey is made, as in cheese-making, it is desirable that it should contain as little fat as possible, as the fat is wanted to enrich the cheese. The following is the percentage composition of whey as given by several authorities:

<table>
<thead>

But when whey is required as a food, it is clearly desirable that at least some of the fat should be retained in the whey, and not be rejected with the curd. This may be effected by a thorough agitation of the curd before straining. Perhaps the most ready way of preparing whey for infant feeding is to use Hawksley’s sterilizing apparatus, as it is provided with a thermometer, and consequently the temperature can be regulated. Thirty ounces of good fresh milk is placed in the bottle provided, and the heat raised to 104° F.; add two teaspoonfuls of pepsin cordial, and set aside for a few minutes. When the curdling has taken place, thoroughly break up the curd by stirring and shaking the bottle; then strain through fine muslin or a colander. In this way 22 or 23 ounces of an opalescent fluid is obtained, which should be heated to 160° F. for twenty minutes, in order to destroy the rennin. It may require a furtherstraining, as more curd is apt to form on heating. Mr. F. Baden Benger, F.C.S., was good enough to make some analyses of whey prepared in this way. He found on an average that the whey contained 97 per cent of proteids, 2 per cent of fat, and 6.1 per cent of salts, the amount of fat being much larger than in whey prepared by simply draining the whey off the curd without agitation. Centrifugalizing, in Gerber’s acid butyrometer, the whey prepared in the wards of the Children’s Hospital, he found an average of 1.75 to 2 per cent of fat.

Whey prepared in this way, with or without an addition of two or three drachms of milk-sugar to the pint, makes a useful food for newly-born infants who have to be artificially fed, or for infants who suffer from chronic vomiting, or have liquid, green, and curdy stools. They will gain weight and be more comfortable than when taking diluted milk. A weak “humanized” milk may be made by adding 10 ounces of fresh milk to 20 ounces of sterilized whey, and adding ½ ounce of milk-sugar. To make a “humanized” milk more rich in fat, use “top-milk” in the same proportion. Let a quart of fresh milk stand in a covered glass jar in a cold place for four or five hours; remove the upper 10 ounces by skimming, and add this to 20 ounces of sterilized whey with ½ ounce of milk-sugar.

If these mixtures are carefully made according to directions, perfectly fresh milk of a good average quality being used, the analysis will work out something like the following; but exactness cannot be expected, inasmuch as much varies in the amount of fat it contains and the time it takes to cream:

<table>
<thead>
<tr>
<th></th>
<th>Proteids</th>
<th>Fat</th>
<th>Lactose</th>
<th>Salts</th>
</tr>
</thead>

It is always well to add a grain or two of bicarbonate of soda to render the mixtures neutral or slightly alkaline.

It is often convenient to give dyspeptic infants whey at first, or even dilute the whey with a solution of maltose or barley-water, as such infants cannot always digest as much as two per cent of fat in their food. As they improve, add milk to the whey, or “top-milk,” as their digestive powers gain strength.

It may be asked, what advantage has whey over a solution of lactose as a diluent? It certainly contains “antiscorbutic” properties, which a solution of milk-sugar does not, and, moreover, it contains soluble proteids and a certain amount of fat. Dr. Ashby has frequently found infants improve and gain in weight after whey has been substituted for sugar-water or barley-water as a diluent for milk, and his experience is strongly in its favor. But more than the average intelligence is wanted in the nursery to carry out details.

FEVERS IN CHILDREN; THEIR SIGNIFICANCE, GENERAL DIAGNOSTIC VALUE, AND ANTIPYRETIC TREATMENT.

The Archives of Pediatrics for April, 1899, has in it an article by S. S. Adams upon this
subject which is of interest. In speaking of the treatment of fevers he tells us that this may be done by the administration of internal antipyretics, in the use of which great harm often occurs. It is true that by a good dose of antipyrin, acetalid, or phenacetin, we can reduce the temperature and make the child apparently better. The parents are satisfied, and we may think we have accomplished something; but what is the result? The effect of internal antipyretics is transitory, and consequently we must resort to one of two things—either allow the temperature to return to its former height, or reduce it by the further administration of powerful antipyretics. In this way we not only confuse the diagnosis, but do much more, for such drugs exert a violent and paralyzing effect on the heart.

Dr. Adams says he does not mean to decry the judicious administration of them, but he believes that antipyrin, in the hands of even the most skilful, is a most dangerous drug. He has seen the ill effects of it, and the apparent good effects. He has seen a child wildly delirious from croupous pneumonia made rational by a dose of antipyrin, so that it could sit up in bed and chat with its parents, but he has seen the same child relapse into a condition of high temperature within twenty-four hours because the heart had never regained the tonicity which it had had prior to the violent reduction of the temperature by antipyrin. His experience with acetalid is similar. With phenacetin he has had a little more favorable results. Of the internal antipyretics it is one of the safest, but it should be given judiciously, and only in those cases in which we require a rapid reduction of the temperature. Its administration should usually be accompanied by free stimulation. These antipyretics act in two ways—i.e., they lessen heat production and increase heat dissipation; and we must take this into consideration in determining the nature of the antipyretic to be given.

The second method of reducing temperature is by the external application of cold. This method is not only the most beneficial, but is the most stimulating to the various systems. It may be done by means of the cold pack, by the application of the ice-cap to the head, or of the ice-coil to the abdomen; but far beyond the beneficial effects of the wet pack and these other methods, the application of the Brand method, pure and simple, is unquestionably the best means of reducing fever, no matter what pathological condition exists. Dr. Adams says this without any hesitancy. He has no compunction whatever in taking from its bed a child having one of the infectious diseases, with a high temperature and accompanying nervous excitement, and placing it in a bath under proper conditions, for he believes that he is not only reducing the temperature but is placing the system in far better condition than prior to the administration of the bath. The Brand method must be carried out in every detail. It is not sufficient to take the little one out of bed and place it in a bath-tub. The bath-tub should be brought to the patient, and the latter should be gently lifted out of bed and placed in the tub, and then the manipulations should be conducted during the bath, and the necessary stimulation given. The result is that the reduction of the temperature is effected with perfect safety.

Dr. Adams has demonstrated to his class in the Georgetown University a case like the following: A child of eight years who was wildly delirious with typhoid fever was placed in a tub containing water at a temperature of 90° F., and kept in this bath for fifteen minutes. Enough heat was dissipated from that child to raise thirty gallons of water 4° F. This shows the immense amount of heat abstracted. The child, who was wildly delirious at the time the bath was begun, became conscious and rational; the pulse increased in force. Quite commonly the temperature rises after three or four hours to its former height, when the bath can be repeated.

In connection with the treatment of acute infectious diseases, Dr. Adams is repeatedly asked why we do not see so frequently the complications and sequelae commonly observed in former years. When he began to practice medicine, as soon as a child was attacked by one of the eruptive diseases, he was isolated, and every crack in the windows of the sick-room was sealed. A blanket was placed over every door but one. The child remained in that vitiated atmosphere from the beginning to the end of the disease, with the result that there was a continual inhalation of a vitiated and germ-laden air. Twenty years ago to give a drink in such a case was equivalent to the physician receiving his passport, so far as that household was concerned. In private practice the complications of scarlet fever, and the post-scarlational conditions, are now much less frequently seen than they were ten or fifteen years ago. It can be attributed not only to
the freer use of water and better ventilation of the sick-room, but also to the practice of placing such fever patients in baths when the temperature requires reduction. Such treatment favors the elimination of the toxic material, and as a result convalescence is more rapid and smooth, and the complications and sequelle are avoided.

The temperature of the bath varies considerably in different cases. With a temperature of 105° we should be very careful how we reduce the temperature of the bath below 95°, the books to the contrary notwithstanding. If we can accomplish what we desire by a warmer bath, and with less inconvenience and discomfort, why should we use a colder one? Some advise a bath at 60° or 55° F., and some even a bath at 50° F. Dr. Adams claims that just as good results follow the use of a bath having a temperature of 95° to 100°, provided a cold cloth is applied meanwhile to the head. The ordinary duration of a bath is ten minutes, and during this time the patient should be subjected to continuous friction. He says he should hesitate a long time before giving his consent to a fever patient receiving a bath at 55°. The city water probably has a temperature of about 50°, so that the effect of such a bath on a normal temperature can be readily tested, by jumping out of bed into water just drawn from the faucet. He is confident that if this is tried a verdict will be rendered in accordance with what he has said.

TREATMENT OF CHOREA BY MASSIVE DOSES OF ARSENIC.

In a Paris thesis of July 19, 1898, Del Pozo records thirty cases of chorea treated by massive doses of arsenic. He considers that these massive doses are far superior to treatment by antipyrin as it is commonly employed, and states that there are two ways in which arsenic may be administered, namely, in small doses very gradually increased, and in large, massive doses rapidly increased up to the point of intolerance, or in other words, until the gastrointestinal canal of the patient rebels, as manifested by vomiting and diarrhea. As soon as these symptoms are developed the dose is cut down day by day until one is obtained which the patient can bear. He asserts that such a treatment usually produces cure within nine days, and that accident from this method is rarely met with. Four cases of arsenical neuritis are reported. Arsenical fever is rare; sometimes arsenical pigmentation occurs, but this speedily passes away as soon as the drug is stopped. —Revue de Thèrapèutique Médico-Chirurgical, January, 1899.

TREATMENT OF ECZEMA IN INFANTS AND CHILDREN.

In the New York Medical Journal of April 1, 1899, Allen expresses the belief that the treatment of infantile eczema is almost exclusively local. The health of these children is usually about the average of those of equal age and social station. In nurslings the mother's breast is taken regularly, or more often irregulately; but aside from this, as we fail to discover vices of table or vicious habits, we cannot fall back upon the much-abused excessus in vino et venere as an excuse for not effecting a rapid cure.

For the scalp affection, and for dry, scaly patches elsewhere, resorcin is useful, as it is in the seborrhoeal forms of eczema in the adult; it is here equally efficacious, but must be used in much decreased strength, as in the following prescription:

Resorcin, 0.5-1.0;
Washed sulphur, 2.0-4.0;
Lanolin, 5.0-10.0;
Lard, ad 100.0.

As an ointment base nothing seems very much superior to the long-tried zinc oxide ointment.

In almost all eczemas about the anogenital and groin region during the past year Allen has been using a three-per-cent watery solution of methylene blue, and can say without hesitation that here, as well as in erythema intertrigo in infants, it has given him most satisfactory results. The drug is somewhat analgesic, is soothing to the irritated, raw, and sometimes ulcerated surfaces, it forms a protective coating, is antiseptic, and from its discoloration leaves no doubt as to the time when a new coat of the solution is required.

In order to keep the parts free from excreta and urine Dr. Allen instructs the mother or nurse to place the infant regularly at each time of feeding, or every two hours, upon a small vessel, with the object of teaching it thus early in life not to urinate in the diaper. If the stream does not follow upon contact of the buttocks with the cold rim of the vessel, the finger-nail or any sharp-pointed object drawn from the bladder region to the umbilicus may succeed in inducing urination. In male children he has frequently accomplished this object by
painting the glans penis with a drop of cold methylene solution. These methods are, at times, useful in securing a specimen of the infant’s urine for analysis, and are much superior to passing a catheter or wringing out a wet diaper.

Methylene blue he has used extensively in a great variety of eczemas, and he believes it a valuable addition to the means of cure. Upon the exposed parts, however, the color is, in most instances, an objection; and in general the staining of the clothing might be a drawback. In point of fact, the parents are so well satisfied with the results that never has this been raised as a serious objection in any case so treated.

The form of seborrhoeal eczema is more rarely pityriasis, with dry desquamation and slight infiltration of the integument. Here mild salicylic and ichthyl applications are of use, as for example:

B Salicylic acid, 0.2–0.5;
Powdered zinc oxide, 10.0;
Powdered starch, 15.0;
Compound tincture of benzoin, 10.0;
Lard, ad 100.0.

M.

Naturally in this, as in any other forms, if any internal derangement is made out, it is to be combated by internal remedies. If there is anemia, and especially if the secretions are inactive, or there is at the same time intestinal fermentation, the following tablet can be given with decided advantage:

B Calomel, 1–10 grain;
Saccharated iron carbonate, ½ grain;
Powdered white sugar, 2 grains.
M. S.: One crushed in milk twice a day.

In older children:

B Iron peptonate, 40 grains;
Elixir of calisaya, 2 ounces.
M. S.: A teaspoonful three times a day.

An occasional larger dose of calomel, a sixth to a fourth of a grain, once a week, is often of benefit.

If the mother of the nursling is a beer drinker or a tea drinker, or if she is in a state of ill health, or suffering from habitual constipation, her condition is to be looked after for the benefit of the little patient.

In the impetiginous form, if the crusts are thick and not readily removed by oil or soft soap, Dr. Allen often orders a favorite cataplasm of the French made with potato flour (pâte de pomme de terre), but he usually orders it made with some antiseptic, such as mild bichloride, carbolic acid, or lysol solution, the latter having the advantage of being somewhat antipruritic.

In the more chronic, i.e., persistent, forms of eruption in older children, and when there are extensive scaly plaques upon the back of the neck, or involving the margins of the scalp regions behind the ears, he uses a stiff, paste-like ointment, as in the formula:

B Resorcin, 1.0;
Tar, 2.0;
Prepared zinc carbonate,
Powdered zinc oxide, 54 10.0;
Lanolin, 50.0;
Lard, ad 100.0.

M.

This is an intermediate prescription between stiff pastes and thin ointments without adhesive properties, and has an advantage over ordinary pastes made with starch in that in the latter, when the fat is absorbed by the crusts, the skin, and the dressings, there is left behind a residue of dry crumbling or caking material, which is apt to act more or less as an irritant, and thus in a measure defeat one of the very objects for which it was employed.

When an impetiginous eczema is impetiginoous because it has been inoculated with the virus of true impetigo, ammoniated mercury ointment, so useful in the latter, is, in modified strength, here likewise efficacious.

The neurotic, nervous, or reflex eczemas, usually of symmetrical distribution, occurring in young children who are florid, fat, and in fit condition, and in whom no error of diet may be discoverable, is an excessively pruriginous affection, requiring primarily applications which will allay the itching and prevent the scratching which is so pronounced an element in the dissemination and aggravation of the condition. Although attributed to the irritation of cutting the gums, it is seen not infrequently in those who have not yet reached the period of eruption of the teeth. Intestinal irritation may be found, especially if the child has reached the age at which certain liberties of diet are allowed. In the majority of cases reliance must be placed almost wholly upon external measures, and one of the most difficult problems to solve is that of retention of applications in situ, and the prevention of injurious scratching and rubbing, especially at night. Dr. Allen has devised for the purpose of retaining dressings upon the head and face a little cap with a mask attached. It is made from a single piece, so that by removing the stitches or safety-pins from a single seam it
can be used as a pattern from which new caps may be cut out. He says he finds this a necessity, since mothers and nurses, however willing, are often unable to manufacture efficient head dressings. Sheet lint or linen is spread with the particular ointment to be applied, in strips of requisite size for the various regions, and over this is placed and securely fastened the cap and mask as devised. Besides this it is necessary to secure the hands to the side by means of safety-pins, attaching the sleeve of the night-dress to the diaper. Whatever rubbing against the pillow is indulged in can then do little more than rub in the ointment applied.

THE VALUE OF STRYCHNINE IN PREGNANT WOMEN.

Tolmatscheff has recorded the results obtained by him in the administration of strychnine in the dose of 1/6 or 1/5 grain twice a day to pregnant women, the drug being given after meals for a period varying from six to ten weeks. He states as a result of his studies in twelve cases that strychnine is a valuable remedy to prevent the atomic constipation of pregnancy, and also that he regards it as being an excellent preventive against feeble uterine contractions. He failed to see any instances in which the treatment seemed to produce disadvantageous results. —Revue de Thérapeutique Médico-Chirurgical, January, 1899.

IS PETROLEUM EMULSION OF ANY NUTRITIVE VALUE?

A reply to this question is made by Hutchison in the British Medical Journal of March 25, 1899. He says that there can be no doubt that in recent years petroleum emulsion has crept into use as a substitute for cod-liver oil in the case of patients who are unable to take the latter. Now, petroleum belongs to the paraffin series—that is to say, to a set of substances which are characterized by the great opposition which they offer to chemical change. One would not, therefore, expect on a priori grounds that petroleum would be capable of assimilation in the body. In order to put the matter to practical test, Dr. Hutchison recently carried out some experiments on the absorption of petroleum emulsion by man, the result of which entirely confirmed the suspicions which he had entertained on chemical grounds, and led to the conviction that petroleum is of absolutely no use at all as a substitute for cod-liver oil. It is the object of his paper to describe these experiments and the conclusions to be drawn from them.

He employed a well known and widely advertised emulsion of exceedingly pure petroleum. It was found that thirty cubic centimeters of it, when mixed with charcoal and evaporated to dryness, yielded on extraction with ether seven grammes of semifluid petroleum; thirty cubic centimeters represents about three dessertspoonfuls, which is the usual daily dose of the emulsion in question. He next proceeded to administer this dose to a healthy man with the object of ascertaining how much petroleum one could recover from the feces. In the first experiment the subject was placed on a constant diet containing a moderate amount of fat. The feces were collected daily, mixed with animal charcoal, and evaporated to dryness. The product was then extracted with ether in a Soxhlet's apparatus and the extract weighed. The results are contained in the following table:

<table>
<thead>
<tr>
<th>First Experiment</th>
<th>Ether extract. Gm.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Total feces of three days without petroleum</td>
<td>7.1</td>
</tr>
<tr>
<td>Total feces of three days on 30 Cc. petroleum emulsion per day</td>
<td>32.7</td>
</tr>
<tr>
<td>Difference</td>
<td>25.6</td>
</tr>
</tbody>
</table>

That is to say, the administration of three dessertspoonfuls of petroleum emulsion daily had increased the ether extract of three days' feces by 25.6 grammes, although the diet was exactly the same as on the three previous days. The appearance of the extract was also quite different for the two periods. That of the first three days was solid and waxy, while that of the three petroleum days was semifluid in consistence.

In order to recover petroleum free from fat the ether extract was saponified by boiling with alcoholic potash solution. The residue was diluted with water, shaken up with ether in a separate funnel, the ether evaporated, and the residue weighed. The total 32.7 grammes yielded on this treatment 21.6 grammes of semifluid petroleum. Now seven grammes of petroleum had been administered on each day, so that 21 grammes had been given, and 21.6 was recovered. The apparent excess found was probably due to the presence of traces of soaps.

In the second experiment no attempt was made to regulate the diet. Thirty cubic centimeters of the emulsion was administered on one day, and the feces of the three suc-
ceeding days extracted with ether, and the extract saponified as above.

SECOND EXPERIMENT.

<table>
<thead>
<tr>
<th></th>
<th>Ether extract. (Gm.)</th>
</tr>
</thead>
<tbody>
<tr>
<td>First day</td>
<td>3.5</td>
</tr>
<tr>
<td>Second day</td>
<td>4.1</td>
</tr>
<tr>
<td>Third day</td>
<td>4.3</td>
</tr>
<tr>
<td>Fourth day</td>
<td>7.6</td>
</tr>
<tr>
<td>Fifth day</td>
<td>6.9</td>
</tr>
</tbody>
</table>

On saponification, the extract of the fourth day yielded 4.5 grammes of petroleum. The extracts of the third and fifth days yielded together 2.6 grammes. The total amount of petroleum recovered was thus 7.1 grammes, while the amount contained in the 30 cubic centimeters of emulsion given was seven grammes. The results of this experiment entirely confirm those of the first.

From these experiments it may reasonably be concluded that petroleum is not absorbed in the human intestine, and Dr. Hutchison considers, therefore, that it can in no wise be regarded as a food or a substitute for cod-liver oil. Nor does he suppose that petroleum has any remote action, say, upon the lungs. It is conceivable that if crude petroleum were employed, some of the volatile substances contained in it might enter the blood and be excreted by the mucous membrane of the air-passages, but the purer the petroleum used the less chance is there of any such occurrence.

Whether petroleum may have any value as a local application in intestinal diseases must be left undecided. One can imagine that there may be conditions of the intestinal mucous membrane in which the administration of petroleum might be of value in the same way as the application of vaselin to the skin, by forming a sort of pellicle on the intestinal surface. In one sense, also, it may be regarded as an artificial intestinal mucus, and it might in that way have some value in certain forms of constipation. It is also worth considering whether it might not be a useful vehicle for the administration of intestinal antiseptics. Carbolic acid dissolves in it, and if the petroleum prevented the absorption of the acid it would also bring the latter into intimate mixture with the intestinal contents, and act as a sort of internal "carbolic vaselin," but that part of the subject would require special investigation by experiment. Dr. Hutchison's only object at present is to point out that petroleum, even when given in the form of emulsion, is not absorbed at all, and as a consequence can have no nutritive value.

PROLONGED CHLORAL SLEEP IN THE TREATMENT OF CHOREA.

The Medical Record of April 1, 1899, contains an article by Lichtschein on this subject. Among the many drugs that have been employed, undoubtedly the most important is arsenic in the form recommended by Romberg. Salicylate of physostigmine, enormous doses of carbonate of iron, chloroform, narcotics, and many other drugs, as well as cold-water treatment, galvanization of the brain and spine, and change of location, have been used with more or less good results. Then, in acute chorea, hygienic measures and changed surroundings, with one or several drugs in combination, will cause a cessation of the disease. But in a small minority of cases all those means mentioned above do not effect a cure, and the disease lasts for years. The patients become exhausted, anemic, and arrested in their physical development, and even their intelligence suffers. What shall we do with these cases?

In the treatment of neurasthenic patients Dr. Lichtschein has for some years employed the rest cure of Weir Mitchell, enforced with the administration of chloral hydrate in doses sufficient to keep them in a somnolent condition. During the treatment of these patients he has observed that their appetite increases, digestion and assimilation improve, and as there is no other kind of energy expended, a rapid gain in weight and strength, and consequently a remarkable abating of nervousness and irritability, result. Furthermore, taking into consideration that choreic movements generally cease during sleep, and that for some time after a night's rest the choreic movements are weaker, and grow stronger only as the day grows older, he came to the following conclusions:

Given a long rest during sleep, and the time of so resting being employed in rapidly strengthening the body, we might have a twofold result: First, the nutrition of the nervous system being improved, the premature discharges of nerve impulses to the muscles may cease; and secondly, the impressions in the nerve centers caused by the centripetal impulses emanating from the agitated muscles may grow weaker and weaker the longer those twitching muscles are at rest, and finally disappear. During sleep, be it natural or artificial, the whole brain and nervous system, with the exception of those parts that superintend the vegetal functions of the body, are at rest. There is no part that need expend more energy than
another; therefore an equalization of vital force in the nerve centers is possible that could not take place if the patient was awake. Though he is in bed and perfectly isolated, he cannot help performing mental work, as thinking, hearing, seeing, etc., which requires the expenditure of as much cell energy as the physical work does, and perhaps more. And now, if during this nearly perfect rest we are able to furnish the means wherewith this equalization of cell energy can be effected —nay, more, if a reserve force can be accumulated—we have accomplished our purpose.

And here, again, sleep is preferable to the waking condition. When the patient is awake we have to contend against his tastes and his discriminations against such foods as we think it necessary to give him, and the digestion in chorea being bad, we must and have to abstain absolutely from crowding food into his stomach. During a somnolent condition caused by chloral we avoid these obstacles; and it does seem as if the chloral acted as an antifermentative and appetite-exciting remedy, for the patients under its continued influence crave for food and assimilate it more readily.

Dr. Lichtschein has observed in the treatment of neurasthenic patients with whom he first employed the prolonged sleep by means of chloral hydrate, that small doses of chloral—five to ten grains every three or four hours—had no effect, did not diminish the restlessness, nor produce sleep. He had to resort to twice, nay, three times, as large doses to have the desired effect, viz., a deeply somnolent condition. It seems that neurasthenic, and to a greater extent choreic, patients need more chloral to become quiet and sleepy than those suffering from other diseases. Still, in giving chloral one has to be very cautious in determining the necessary quantities to be used. It is well to give one single dose, say ten to fifteen grains, first, and if sleep is produced to determine from the depth and duration of the sleep the dose of the drug and the time at which it is to be repeated. If the first dose does not cause sleep, increase the dose until sleep is produced and determine as above. The sleep should be superficial enough to allow patients to respond when loudly spoken to, and still be sufficiently deep to keep them quiet.

One would raise the objection that chloral is a dangerous remedy, is a heart depressor, and that its continued use would weaken the heart; but by giving at the same time small doses of strychnine and watching the pulse and respiration, and immediately reducing the dose of the chloral if the former is greatly accelerated and the latter has become less frequent, the author has, in the cases of neurasthenia treated by this method, never observed any bad effects whatsoever, either during the sleep or after the patients were awake. He has treated with this prolonged sleep three cases of chronic chorea, in all with excellent results.

**Nephritis Complicating Acute or Subacute Gastroenteritis of Infants and Children; Its Treatment.**

Koplik states in the *Medical Record* of April 1, 1899, that the treatment and management of these cases is practically the management of all severe forms of gastroenteritis. We should never lose sight of the fact that opium in any form, mercury, and the coal-tar products, designed to disinfect the intestinal tract, like benzol, salol, carbolic acid, and guaiacol, are ruinous; they only tend to deepen the toxemia, and by irritating the kidney intensify the functional disturbance in that organ.

In all these cases the suppression of urine, the rapid emaciation, are manifestly the result of the withdrawal from the tissues and blood of a vast amount of the fluid elements. It is granted that the irritation of the kidney elements is due to infectious material circulating in the blood, but in these cases also the concentration of the toxins, and thereby the total suppression of the urine, may be favored by their presence in concentration due to the great loss by the system of its watery elements. The full and free supply of water through all the possible channels is one of the greatest means of placing these cases on a convalescent basis.

Stomach washings should be daily employed, and also rectal irrigations. In the latter Dr. Koplik has employed Cantani's physiological solution (sterilized water 1 quart, sodium chloride 1 drachm, sodium carbonate 45 grains, at a temperature of 38° to 40° C.). This solution was also made use of in hypodermoclysis. For making a rectal irrigation in the infant in the severe cases cited, he employed an adult size stiff-rubber rectal tube. A small catheter is worse than useless. It doubles up on introduction in the lower rectum. The child is completely undressed, shielded with a blanket from ex-
posure, and the buttocks are raised high. The rectal tube is introduced high up the gut, and a quart or more of the above solution is thrown into the rectum and allowed to flow out at intervals, so as to clear out what little fecal matter there may be in the lower gut. The irrigation is so managed that a large amount of fluid is left in the gut after the withdrawal of the tube; in other words, we make an effective enteroclysis. We do this daily. In the very severe cases he introduces daily 200 cubic centimeters or more of sterilized physiological salt solution under the skin of the abdomen (hypodermoclisis). The medical treatment is confined in these cases to the exhibition by the stomach of bismuth in large doses.

In all cases the milk (artificial or breast) is suspended, and the child fed on albumen-water or beef juice mixed with sterilized barley-water. Inasmuch as the barley may in cases be moldy, Dr. Koplik has lately prohibited its use, as it seemed in some cases to aggravate symptoms. The so-called acorn cocoa has been a useful food substitute in many cases.

If one stops to study the above, he will see that the treatment of severe gastroenteritis has been only outlined, but in so doing a defense has been found for the application of these measures in the state of the kidneys, and it has also been shown how the use of drugs formerly much in vogue must finally injure these patients. Take, for example, the simple use of opium. Dr. Koplik has always warned against its use in any form in these cases. The physician would defend its use on the ground that it quiets the patient. This is so, but the quiet thus produced is a stupor analogous to the stupor in cases of uremia in which too much morphine has been made use of. Such a case he had occasion to see lately in consultation. He warned against opium. It was used, and the babe never roused itself from the stupor which he believes was brought on by its use, and which was intensified on account of the vulnerable state of the kidneys.

Sublimate also, even in smallest doses, is a dangerous drug in these cases of gastroenteritis, as is also calomel in repeated doses of one-tenth grain, such a favorite with many physicians. In closing: Koplik speaks of the beneficial effects of warm baths with massage in the bath, and the cautious use of strychnine to stimulate the heart. He does not use alcohol in these cases.

In thus evolving the treatment for these severe forms of gastroenteritis, he has shown how step by step scientific medicine has advanced to protect the little patients from the injurious effects of the former indiscriminate and blind use of drugs of all kinds and most diverse action.

THE TREATMENT OF EXCESSIVE SWEATING.

An article on this subject is published by Weber in the Journal des Praticiens of March 11, 1899. He points out that in certain conditions where there is localized sweating or hyperhidrosis, that it is chiefly a neurotic condition and is to be treated usually by the administration of bromides, antispasmodics, and, more important than all, cold douches, which will improve the nutrition of the nerves and vessels in the part affected. Of course, where alcohol, tobacco, cocaine, or similar substances are used to excess, these must be withdrawn.

In the sweating which accompanies general diseases such as the various fevers, the following treatment may be instituted:

Agaric, 45 grains;
Extract of opium, 7 grains.

Make into 40 pills and take two or three at night.

Or, in other cases, pills of agaracrin, in the dose of one-tenth to one-fourth grain, may be given. In other instances tribasic phosphate of lime in the dose of one drachm is useful. In still others camphoric acid in the dose of twenty to forty grains, given in powder, in capsules, in konseal, or dissolved in brandy or whiskey. The other remedies which are not to be forgotten in this condition for obstinate cases are ergot, picROTOXIN, and sulphonal.

Locally lotions of tannin one per cent, alum ten per cent, may be applied, or a powder may be put up for internal use as follows:

Pulverized talc, 3 ounces;
Salicylic acid, 20 grains.

Local sweating of the feet or hands may be controlled by applying three times a day the following formula:

Borax, % ounce;
Salicylic acid, % ounce;
Boric acid, 1 drachm;
Glycerin,
Dilute alcohol, of each 2 ounces.

In cases of fetid sweating of the feet the following may be used:
Pulverized talc,
Subnitrate of bismuth, of each \(\frac{1}{4}\) ounce;
Permanganate of potassium, \(\frac{1}{4}\) grain;
Salicylate of sodium, 30 grains.
Apply over the feet and dust between the toes.

Or,

Powdered alun, 45 parts;
Salicylic acid, 5 parts.

It is hardly necessary to add that in the profuse sweating which occurs at the crisis in such diseases as pneumonia we should abstain from interfering with it. Only when the sweating becomes more or less chronic should it be arrested.

**DIABETES MELLITUS.**

Graham Brown, in the *Scottish Medical Journal* for March, 1899, tells us that it is a matter of considerable importance that a man suffering from diabetes should lead, as far as may be, an easy life free from worries. If possible, he should give up any occupation which involves mental anxiety, as he is as a rule quite unfit to stand any strain of that kind, and such anxiety will tend to hasten the progress of the disease. The skin, as has already been said, is very dry, and it is of some importance therefore to excite its functions either by means of tepid baths, or, if the diabetic condition is not a severe one, by mild Turkish baths. He should wear flannel or silk next the skin, and he should take as much exercise in the open air as he can stand without undue fatigue.

The most important point, however, in regard to treatment is that of diet. The object, of course, is to reduce the carbohydrates as far as may be. It is not possible to do this absolutely for any length of time, but by careful selection of the food the amount of starch taken may be reduced to a very small quantity. It is, of course, necessary that one should in each case write out and give to the patient careful directions as to diet, and one should remember that after a time diabetic diet becomes very distasteful, and it is of great importance to vary the food as much as possible, and by means of alterations in the method of cooking, to tempt the palate. The following will give one an idea of the lines on which one should proceed in this matter. Of solids, the patient may take meat of any kind—fresh, salted, or even smoked—except liver; fish of all kinds, including shell-fish; poultry, game, rabbits, eggs, butter, cheese, lettuce, tomatoes, asparagus, watercress, celery, cucumber, mushrooms, and the various kinds of diabetic bread, provided these are reasonably free from starch. In small quantities the patient may take lemons, oranges (if not sweet), currants, and cranberries. Subject to the reservation to be mentioned presently, all farinaceous preparations should be forbidden, also bread, rice, tapioca, semolina, arrowroot, and the like. Peaches, turnips, asparagus, vegetable marrow, beet-root, green peas, cauliflower, all sweet fruits, and sugar in any form are likewise inadmissible.

Of liquids the patient may take water, aerated water, tea, coffee, soups which have not been thickened with farinaceous material, and, if one gives a stimulant, a little light claret or a very little whiskey may be allowed. Milk may be also taken, but only in comparatively small quantity. The consumption of sweet wines and liqueurs, of cocoa and chocolates, and of beers and ales should be forbidden. The great difficulty is as regards bread, for which diabetic patients have an exceeding fondness. Diabetic bread is not very pleasant as an article of food, and sometimes we are obliged to allow a little ordinary bread. It is best taken as thin toast, rather over-toasted. In diabetic cookery, saccharin may take the place of sugar.

The various diabetic foods which are sold are not, as has been said, very palatable, and in the case of many of them, if one has them analyzed as we should do, we will find that they are by no means as free of starch as is represented. One has, therefore, to be careful in the selection of the almond, gluten, or cocoanut cakes which we allow the patient to have.

In some cases of diabetes, certain carbohydrates can be taken without harm. Kulz showed, many years ago, that in diabetics the liver frequently retains the power of transforming levulose into dextrose, and consequently both levulose and the nearly allied inulin have been used in the diet of diabetics. Regarding the latter of these, however, the careful observations of Sandmeyer show that it is very indigestible. Levulose, which can be readily obtained commercially, may very properly be made use of in diabetic diet, care being taken to ascertain that the amount of sugar in the urine is not thereby increased.

Now while in every case of the severe form of diabetes a somewhat rigorous diet requires to be adhered to if the disease is to be held in any way in check, no such severity of dieting is necessary in the lighter cases. Indeed, sometimes when the sugar is small in qua...
tity and is associated with gout, all that is
needed is that the patient should be given a
diet suited for that malady. And between
these two extremes all sorts of intermediate
conditions may be found. That is, one may
often encounter cases in which, though much
starch occasions glycosuria, a small quantity
will not do so, the amount of disturbance of
the glycogenic function being slight. It
therefore becomes one's duty to discover—
in case of any individual patient—how much,
if any, starch he can consume without in-
crease of sugar in the urine. He should be
put at first on a very strict diet, and after a
week or so, when the quantity of sugar pres-
ent in the urine has become stationary, he
should be allowed to take a certain small
quantity of starchy food. If no increase of
sugar results a little more may be given, and
in this way one learns what quantity of starch
it is safe to give.

Patients who can afford to visit Vichy or
Carlsbad, and to whom a few weeks spent
abroad are not distasteful, may very well be
sent to one or other of these places, provided
only that the disease is not too far advanced.
Dr. Brown has seen very marked benefit fol-
low a course at both these spas.

The medicinal treatment of diabetes is not
very hopeful. Opium has been much used,
and sometimes great benefit follows its em-
ployment. It usually has to be given in
rather full doses, and a remarkable diminu-
tion of the sugar in the urine may then be
observed. Sometimes morphine may be found
to suit better, and codeine is likewise fre-
quently employed. Benefit may also be found
to follow courses of arsenic. This remedy
should be given in gradually increasing doses
and for a considerable period of time. Many
other remedies have been employed, such as
lactic acid, glycerin, iodoform, antipyrin,
phenacetine, salicylate of soda.

There remains only one point to note, viz.,
that in regard to the use of extracts of the
pancreas, if, as we have reason to believe,
destruction of the pancreas is followed by
the symptoms of severe diabetes, it would
seem logical, in the light of the results ob-
tained with the thyroid gland in cases of
myxedema, to expect great benefit from the
administration of extracts prepared from the
pancreas. Unfortunately, however, this is
not the case. Pancreatic extracts have been
administered many times, but it is seldom
that any distinct effect has been obtained.
What the reason of this is we cannot tell.
It may be that the particular ferment of
which we are in need has been destroyed in
the preparation of the extract, or has been
broken up by the juices of the stomach be-
fore it could be absorbed. However that
may be, it is to be hoped that in the not far
distant future some method of preparation
of pancreatic ferment and of its administra-
tion may be discovered, which shall prove
useful in the cure of diabetes.

SULPHONAL POISONING.

A case of sulphonal poisoning is reported
by Gulland in the Scottish Medical Journal
for March, 1899. In discussing this case he
takes up: (1) The clinical history of sulpho-
nal poisoning; (2) the differences between
this and acute sulphonal poisoning; (3) the
pathology of the two conditions; (4) their
treatment; (5) the conditions under which
sulphonal should and should not be used.

1. Clinical History.—One must carefully
distinguish, as Friedländer was the first to
do, between the by-effects which may appear
after patients have taken sulphonal, and
which are due to a temporary effect of the
drug, and those more serious symptoms
which are the result of its cumulative action,
and alone deserve the name of poisoning.

The former usually appear on the day
after a medicinal dose of sulphonal, and
include headache, tinnitus, muscular weak-
ness, feeling of fatigue, continued sleepiness,
giddiness, loss of coordination, and some-
times a scarlatiniform rash. The percentage
of persons in whom one or other of the
symptoms occur is not very large, and as a
rule they pass off rapidly, with the occasional
exception of the disturbance of coordination.

Chronic poisoning does not set in unless
the patient has taken at least several medi-
cinal doses, and usually not unless he (or she
rather, for women are much more frequently
affected than men) has been taking the drug
for a month or so. Schulz’s fatal case was
in a woman who had only had fifteen grains
of sulphonal sixteen times in a month—an
allowance which many people exceed—but
Dr. Gulland can find no other fatal chronic
case where so small an amount was taken.

As a general rule the first symptoms to
appear are gastrointestinal—anorexia, thirst,
nausea, vomiting, and especially constipation,
which may be followed by diarrhea. There
is sometimes cardiac weakness; there may be
a skin eruption; the temperature does not
seem to be specially affected, as both rise
and fall have been observed. Soon after the
gastric symptoms, as a rule appear nervous symptoms, of which the most marked are ataxia of the extremities and a staggering gait, sometimes, though not so often, paralysis of the extremities or of facial muscles, and in very severe cases localized or general convulsions. Mental apathy and depression, with anesthesia of the skin, often come on along with the motor symptoms, and in the fatal cases pass on to coma before death. Drowsiness is not a very prominent symptom in most cases until the final stage is reached. Sometimes early, sometimes later, appear changes in the urine, at first a diminution in its amount, then sometimes albuminuria, and especially that symptom which has come to be generally associated with sulphonal poisoning — hematocephoryninuria — the excretion of deep-red urine, which owes its color to the pigment hematocephorynin. This urine is always intensely acid, and contains unchanged sulphonal.

Though it is evident that the hematocephorynin must be derived from the hemoglobin of the blood in some way, we know very little about the condition of the blood in these cases. Some observers have found a diminution in the number of red corpuscles and a fall in the percentage of hemoglobin, but the difference from the normal has seldom been very great, and many of the people in whom the poisoning occurred were very likely the subjects of a certain amount of anemia. More will be said of this in discussing the pathology of the condition.

The case which Dr. Hulland has narrated was a fairly typical one, and was terminated, as most of them are, by heart failure.

2. The differences between chronic and acute sulphonal poisoning are very considerable. The symptoms appear rapidly after a single large dose, taken by accident or for suicidal purposes as a rule. Sleep comes on, and sometimes a prolonged sleep lasting for days and followed for a time by giddiness is the only evil effect. Sixty grains has produced a sleep lasting seventy-five hours, and in one case a woman who had taken thirty grains slept for forty hours, could not be awakened, and died at the end of that time.

In most cases which recover there are some after-effects — gastrointestinal disturbance, muscular paralysis, ataxia, nephritis—which last for a longer or shorter time, and are not dependent on the amount which has been taken. It is curious, however, that hematocephoryninuria only occurs, if it occurs at all, very exceptionally in the acute cases. With this may be noted the fact that in almost all of the acute cases in which the blood has been examined no abnormality has been found, or if any change was noted it was simply a diminution in the percentage of hemoglobin, which need not have been due to the sulphonal.

The prognosis in the acute cases is relatively much better than in the chronic ones; if treatment is begun early one can almost depend on saving the patient, while a pronounced case of chronic poisoning can hardly recover.

To recapitulate briefly, the symptoms in chronic cases are usually, first, gastrointestinal, especially vomiting and constipation, then nervous ataxia and depression, passing into a sleep-like coma, and with that albuminuria and hematocephoryninuria. If the patient recovers these symptoms pass off, the hematocephoryninuria being usually the first to disappear, and some nervous symptoms generally remaining longest. In acute cases the first and prominent symptom is sleep, and only when that has ceased do the other symptoms become evident. They usually pass off entirely after some time and leave the patient well.

3. The pathology and pathological anatomy of the condition depend on the facts that sulphonal is not readily soluble, that it may remain for a long time in the alimentary tract, that it or its products may also be retained in the blood and cause changes there, and that it is ultimately excreted by the kidneys. It will at once be seen that any weakness, functional or organic, along its line of march will favor the occurrence of chronic poisoning on the one hand, or add to the dangers of acute intoxication on the other. Thus constipation favors poisoning, and we find that almost all the fatal chronic cases have occurred in people who were habitually constipated. Any affection of the liver, of the blood or heart, and, at the other end of the chain, of the kidney, will assist in the accumulation of the sulphonal in the body and enable it to produce toxic effects. There is no doubt that accumulation takes place in perfectly normal people. Morro has shown that after a few doses have been taken the amount excreted unchanged in the urine becomes larger every day, and when the drug is stopped unchanged sulphonal is excreted in the urine for at least three days.

Let us follow the drug in its course through the body, and see what changes are produced in the different organs. The stomach and
intestines are said sometimes to show superficial necrosis, and Stokvis believed, from his experiments on, rabbits, that hemorrhages often occurred in the gastric and intestinal walls. These, however, are common in rabbits and not peculiar to sulphonal poisoning in them. In the liver congestion has always been found, and sometimes the cells are broken down; they are always more or less fatty, but Dr. Gulland has nowhere else found described the degeneration of the walls of the portal vein which he has noted. The heart has generally been found to be fatty, and from its weakness result the various signs of stasis which he has described in the lungs and spleen of his case, while Hoppe-Seyler and Ritter refer the occasional bronchopneumonia to the aspiration of food particles into the lungs during the coma.

With regard to the changes in the kidney there is a striking unanimity of opinion. The chronic cases of Marthen and Stern showed exactly the same destruction of the secreting cells which Dr. Gulland has described, the acute cases of Hoppe-Seyler and Ritter and others presented it, and it has been produced experimentally in animals; so that it seems to be an invariable phenomenon. It accounts, of course, for the oliguria and albuminuria, and for the tube-casts which have often been found in the urine of both chronic and acute cases.

The hematoporphyrinuria is much more difficult to explain and has roused the interest of many observers. Hematoporphyrin, or iron-free hematin, is derived from hemoglobin when it is acted on by acids in the absence of oxygen. Hemochromogen is first formed, which then loses its iron and becomes converted into hematoporphyrin. It has been usual to assume that hematoporphyrinuria is causally associated with sulphonal poisoning and that it has to do with the frequent fatal issue, and to assume as a result of this that sulphonal is a blood poison in the sense in which either chloride of potash or anilin is a blood poison. But it appears to have been overlooked that sulphonal can kill without the production of hematoporphyrinuria, and without causing any reduction in the number of red corpuscles or the percentage of hemoglobin; for, as Dr. Gulland has already said, hematoporphyrinuria does not appear in the acute cases, nor in those acute cases in which it has been examined has there been any change in the blood. In several of the chronic cases, it is true, anemia has been found, but it has always been the kind of anemia which is likely to occur in the course of a parenchymatous nephritis—a slight diminution of the red corpuscles and a rather greater diminution in the hemoglobin, without any marked change in the leucocytes. The facts, besides the hematoporphyrinuria, which make one think of sulphonal as a blood poison are the fluidity of the blood and the ease with which the red corpuscles become transformed into shadows. The patients never looked specially anemic; they were never cyanosed as in anilin poisoning, and it would seem that the cause of death in both the acute and chronic cases should be sought in the kidney condition which is common to both, and which must certainly involve retention of products which should be excreted. It seems, in fact, that the cause of death is probably a uremia, using the word in its widest sense, whose symptoms are masked by the effects of the drug. We must remember, too, that as von Mering has shown, it is impossible to produce hematoporphyrinuria at will, either in animals or man, even by giving large doses to animals for a long time, and though these animals are poorly nourished and acids are given along with the sulphonal, and the condition occurs in the most capricious way.

Nakorai has recently shown that Stokvis was right in saying that hematoporphyrin was present constantly in the urine of patients suffering from lead poisoning, but the only other condition where hematoporphyrinuria is at all constant is in hemorrhage from the intestine. Otherwise it is rare, though there seems to be small traces of hematoporphyrin in many normal urines. There seems a possibility that both in lead and sulphonal poisoning the hematoporphyrinuria may be due to intestinal hemorrhage, but we know so little about the way in which sulphonal is absorbed, or even what are its decomposition products in the urine, that it is impossible to dogmatize on the matter. Kast's original view that it is excreted mainly as ethyl-sulphonic acid is not now widely held. Von Mering suggests that it may be excreted as amido-derivatives of ethyl-sulphonic acid. Certainly the urine is always strongly acid, and equally certainly hematoporphyrinuria can be controlled by the free use of alkalies.

Dr. Gulland states that he is far from saying that sulphonal may not sometimes act as a blood poison, and that the hematoporphyrinuria may not partly be due to that, but there must certainly be some other factor at work of which we as yet know nothing, and
which determines that in one case a patient shall take sulphonial for months or years unharmed, while another dies in a month from the time the first dose is taken.

It is somewhat curious that in Dr. Gulland's case, though the kidney was so seriously affected, no albumin was found in the urine by any of the ordinary tests. The explanation seems to be that there must have been complete suppression of urine secretion for some time before death, probably for twenty-four or thirty-six hours, and that the urine which was drawn off by the catheter was the product of the kidneys before they became so seriously affected. At the post-mortem examination only half an ounce of urine was found in the bladder, although it was about ten hours since the catheter had been passed, and that amount might easily have been left in the bladder after that operation. Dr. Gulland suspects there had been complete anuria for some time before death.

He says he cannot explain the condition of the blood, especially the presence of so large a percentage of lymphocytes in the films, as he has made no special observations on the state of the blood found post mortem in the heart. There certainly must have been some anemia during life, or the few nucleated red corpuscles and poikilocytes would not have been present; but equally certainly the anemia could not have approached in degree that in a pernicious anemia, or even that in the acute anemias, as, for example, that of septicemia. It is, of course, possible that the sulphonial or its products may in some way alter the hemoglobin of the corpuscles or alter the blood plasma, without causing a very extensive breaking down of corpuscles; but the mystery still remains unsolved, why it exerts its action as a blood poison only in certain individuals, and only when it is allowed to act as a chronic and cumulative poison.

4. The treatment of the two forms of poisoning may be summed up as follows: In the acute form, as the poison is absorbed but slowly, the stomach should be emptied if the patient is seen early enough, or the vomiting which is often present may be encouraged. Later, purgatives may be given to remove as much as possible of the drug from the intestine, and all possible means be tried to keep the kidneys acting freely. Neisser saved his case, where 1500 grains had been taken in a single dose, by giving large enemata of warm water frequently repeated, which produced free diuresis; and it would probably be well to try this again. Other treatment must be symptomatic.

In the chronic form, while it would be well to clear out the bowels and to promote diuresis, the best results have been obtained by giving large doses of alkalies, as Muller did, in such quantities as to render the urine alkaline if possible; probably both the bicarbonates and either the acetates or citrates should be given. As before stated, unless the chronic cases are very slight, the prognosis is very bad. Alkalies control the hematoporphyrinuria, and where their use has been stopped too early the red coloration which had entirely left the urine has returned.

5. Indications and Contraindications.—It is not worth while to speak of the indications, for upon making inquiries it will be found that probably more sulphonial is used than all the other hypnotics put together, so that it evidently meets a felt want. It has the advantage of giving a very restful sleep; and as most people probably only use it now and again, so that plenty of time is allowed between doses for elimination, there is no great danger in its use in the majority of cases.

It should not be given in cases where there is great prostration, in cases where there is gastrointestinal disturbance, especially if this takes the form of constipation, in cases of heart disease, in old people, or where there is a parenchymatous kidney lesion, acute or chronic. The maximum daily dose for a man should be thirty grains, for a woman fifteen to twenty grains; and it should never be given continuously, but pauses of at least three or four days should be allowed from time to time to permit elimination of the accumulated drug. It should never be given in the solid form, both because it is less quickly absorbed, and acts less quickly in that way, and because it is more likely to cause gastrointestinal disturbance. It is most soluble in hot alcohol, so that hot whiskey toddy is probably the best medium in which to give it; the next best, hot water.

The occurrence of any symptoms of chronic poisoning should be an indication to stop its use at once, and no patient who requires to take sulphonial for a long period should be allowed to pass out of observation. It is one of the disadvantages of the tabloid method of putting up drugs that patients can get such drugs as sulphonial without difficulty and can continue their use without let or hindrance.

In cases where a hypnotic of the class to
which sulphonal belongs is required, and
where it is not desirable to use sulphonal,
trional may with advantage be employed.
Sulphonal is di-ethyl-di-methyl-sulphone-
methane, and trional is derived from it by
the substitution of another-ethyl radical for
one of the methyls. It is much more soluble,
and consequently acts in a smaller dose,
more quickly, more certainly, and without
leaving the unpleasant after-effects of sulpho-
nal. Though it is not absolutely free from
the risk of causing chronic poisoning, it is
much less likely to do so than sulphonal, as
it does not accumulate so much. Its only
relative disadvantages are that it costs about
twice as much as sulphonal, and that it has
a more unpleasant taste. It is displacing
sulphonal largely in Germany, to judge by
the opinions quoted by von Mering, but
shows little sign of doing so in this coun-
try.

Dr. Gulland does not consider that sulpho-
nal should be regarded as a dangerous drug,
but he would plead for greater caution in
its use and especially for greater discrimi-
nation in the choice of the cases where it is
to be employed. Its apparent capriciousness
of action is its chief danger, and a drug
which has a recorded death-roll of at least
thirty cases, and probably many more un-
recorded, is not one which should be recom-
manded with a light heart to the first-comer.

GLONOINISM.

While we are all more or less acquainted
with the effects of nitroglycerin when intro-
duced into the system in medicinal doses, we
are perhaps not so familiar with the peculiar
conditions it produces when absorption takes
place by inhalation and through the skin in
doses the size of which we have no means of
ascertaining, but which may be enormous.
Observations, therefore, of a class of patients
of this kind, carefully made and covering a con-
siderable period of time, cannot fail to prove
interesting. In International Clinics for Janu-
ary Dr. Geo. C. Laws has reported a number
of cases of intoxication by this agent, to which
condition he has given the name “Glonoin-
ism.” His experience was obtained among
the workers in a nitroglycerin factory during
the past twenty years, where many of the em-
ployees are compelled to handle thousands of
pounds of nitroglycerin a day, and the hands
and arms as far as the elbows are covered
with it, frequently for hours at a time. Nat-
urally absorption through the integument, or,
as is now believed, some volatilization and
absorption through the lungs, occurs. In
either case the result is the same; the drug
exerts its action upon the arterial system
through a paralyzing action upon the vaso-
motor system. The left ventricle dilates as
well as the blood-vessels themselves. Con-
sequently the pulse is soft and compressible,
though usually full, and is somewhat accel-
erated. Palpitation of the heart is common,
and with it a corresponding throbbing of
the arteries, which latter being most appreci-
ated in the vessels of the brain gives rise to
a severe throbbing occipital headache to
which the name “powder headache” has
been given. The dilatation of the arteries
results in a marked reddening of the entire
body surface, though with an increased poi-
soning some failure of circulation ensues and
cyanosis more or less profound succeeds.
Among others of the initial symptoms may
be mentioned nausea and vomiting, diarrhoea,
more or less prostration with great languor,
and eruptions of various kinds.

After a lapse of a week or ten days a sort
of immunity, as far as the “powder head-
ache” is concerned, is acquired by the new
man; but as the drug is thrown off very soon
after absorption, the immunity is by no
means lasting, and a few days’ absence from
work is sufficient to destroy it entirely. In-
deed, some of these men suffer from the
“powder headache” every Monday morning.
These symptoms, which might be called acute,
are unfortunately not confined to those actu-
ally engaged in the work. The wives and
children, friends, and even medical attend-
ants suffer. The wives, if they attend to the
laundry, are usually attacked every wash-day,
and ironing is particularly liable to precipi-
tate an attack on account of inhaling steam
from the clothes. In time these women
may acquire a comparative immunity, but
still they usually suffer to some extent when
ironing. Dr. Laws states that he himself, as
well as his colleagues, has frequently had
attacks of the headache, even after a short
physical examination of the chest. Among
the children, especially the younger ones,
several deaths have undoubtedly been due to
their having slept with their parents and in-
haled the exhalations from their bodies.

Following the acute trouble, by a greater
or less period of time, a chronic condition of
dilatation of the heart and of the entire
arterial tree supervenes. This varies much
in degree, depending upon the amount of
the substance handled each day, the length
of time exposed, and the individual resisting power; but it is present to some extent in all. The symptoms vary with the degree of dilatation; in mild cases an accentuated first sound with diffuse apex-beat is present; then arrhythmia, palpitation, shortness of breath on slight exertion; finally, incompetency of the valves with regurgitation of the blood, as indicated by murmurs over the various valvular seats. With this condition there may be any of the accompanying symptoms of impaired cardiac action. As far as the nervous system is concerned, there is usually a certain amount of mental hebetude, and especially is this the case during the working hours. A peculiar feature is the action of alcohol upon the victims of glonoinism, a small drink of whiskey often bringing on the symptoms of the primary attack of which we have spoken. The women are also subject to chronic glonoinism, and while the same course may be followed as in the case of their husbands, as a rule the symptoms are not so severe. With them, however, exophthalmic goitre is by no means uncommon; and menorrhagia and metrorrhagia, miscarriages, premature births, and comparative sterility are all more common than among their sisters not influenced by these peculiar conditions. The children of these people are far from strong, as compared with other children of the neighborhood, and are able to offer but little resistance to the onslaughts of disease, particularly infectious diseases and catarrhs.—Journal of the American Medical Association, March 25, 1899.

A SECOND CASE IN WHICH RECURRENT MAMMARY CANCER DISAPPEARED AFTER TREATMENT BY OOPHORECTOMY AND THYROID EXTRACT.

Dr. Herman published in The Lancet of June 11, 1898, a case in which recurrent mammary cancer had disappeared after oophorectomy and the continued administration of thyroid extract. He now adds (Lancet, April 22, 1899) to that report that the patient continues in good health (April, 1899), has no sign of recurrence, and has gained about five pounds in weight since that report was written. He also corrects an error in the report. It was said that the tumor was not examined microscopically. It was examined and found to be indubitably cancer. He has now to report a second case in which similar treatment has been followed by a like result.

The patient had had three children and two miscarriages, the last pregnancy being fourteen years ago. She first noticed a lump in her right breast towards the end of 1894, she being then aged forty-five years. In May, 1895, she went to the Middlesex Hospital, and on June 7 Mr. George Lawson removed the right breast with the fascia covering the pectoral muscle and four enlarged axillary glands. The growth on microscopical examination proved to be carcinoma. On October 21 of the same year she was readmitted with three nodules situated just beneath the scar and just external to the anterior axillary line, and two others just above the center of the scar. There were also further lumps in the axilla, which were thought to be enlarged glands. The nodules and enlarged glands were removed on October 23. The patient stated that "the old wound reopened" in April, 1896, and from that time continued to discharge. In November, 1897, she noticed a lump in the left breast. She was admitted into the London Hospital on July 11, 1898. There was then an ulcerated surface over the third and fourth ribs, depressed at its center and fixed to the subjacent parts, with thickened margins. Its general shape was that of an oblong with spurs projecting here and there, the dimensions of the oblong being three and a half inches by one and a half inches. The right axilla was a depressed cicatrix fixed to the rib below, separate from the ulceration and without sign of recurrence of cancer. In the left breast was a lump of stony hardness which measured with calipers (the skin over it being therefore included) three and a half inches by two inches. The left nipple was drawn in, and there were hard, enlarged glands in the left axilla. The patient had menstruated regularly until six months before admission. Since then menstruation had been irregular, the last time being three months before admission.

On July 12 both ovaries were removed, and as soon as the vomiting caused by the anesthetic had subsided the patient was put upon thyroid extract, five grains three times daily. This she has taken ever since. She left the hospital on August 5. Her weight was then 12 stone 2½ pounds. She came to report herself on September 15. The ulcer had completely healed. The left breast was much softer. Her weight was 13 stone 7½ pounds. She was next seen on October 14. The scar in the right axilla was movable. There was no distinct lump in the left breast,
and there were no enlarged glands in the left axilla. On March 28, 1899, her weight was 14 stone 10 pounds. There were some keloid-like nodules in the scar, but these had not grown and showed no tendency to break down. The left breast presented the characteristics of health, except that the nipple was retracted. Her right arm and hand swelled occasionally after scrubbing, but this had been the case since the first operation.

Two points call for comment. First, as to the relative importance of the two parts in the treatment—oophorectomy and thyroid extract. Mr. Stanley Boyd thinks that oophorectomy alone will explain the benefit in Beaton’s cases. He has treated seven cases and Mr. Watson Cheyne two by oophorectomy, but in only one was there benefit great enough to be called cure. He has collected six other cases in which the information given was not enough to enable the cases to be tabulated, and out of the whole fifteen, in only four was there “relief worth obtaining.” In the face of this experience Dr. Herman says he cannot agree with Mr. Stanley Boyd in thinking that oophorectomy alone will explain the benefit.

Mr. Stanley Boyd has published five cases in which thyroid extract was given. In one it was only given for a month; in another it was not begun till oophorectomy had failed and recurrence had taken place; in three other cases he gave thyroid extract to patients whose ovaries had not been removed, and in two of them some benefit seemed to follow.

Page and Bishop have published a case in which cure followed administration of thyroid extract. Four cases have now been published of cancer treated by oophorectomy plus thyroid extract, and in three of them the cancer disappeared.

Dr. Herman submits that the evidence at present before the profession goes to show that greater benefit results from the combination of oophorectomy with thyroid extract than from either of them separately, and that it is desirable that the effects on cancer of the combination of oophorectomy with thyroid extract should be tested as fully as possible.

Next, as to the word “cure.” No one can say that these patients have been in the strictest sense of the word “cured” until they have been watched through the remainder of their lives. But Dr. Herman submits that to make cancer disappear is a much greater thing than to mechanically remove it with the knife; and if we can maintain that condition of the organism which led to the disappearance of already formed cancer tissue, we may reasonably expect that this condition will be incompatible with return of cancerous growths. These patients cannot develop new ovaries, and they have been instructed to take thyroid extract for the rest of their lives. If they do so, Dr. Herman thinks there is a sure prospect of freedom from cancer. In conclusion, he asserts that oophorectomy plus thyroid extract has given results which have not been approached by any other treatment of recurrent mammary cancer.

PREGNANCY AND THE THYROID GLAND.

During pregnancy, and even to a slight extent during menstruation, the thyroid gland undergoes more or less pronounced enlargement. This becomes noticeable toward the fifth month of gestation, and continues until the end of the puerperal period; and it is a physiological fact to which, perhaps, sufficient attention has not been paid, for it may possibly help to explain a whole train of nervous symptoms of which, so far, no explanation has been attempted. The first question that suggests itself is whether the enlargement is due to simple hyperemia or whether it is a genuine hypertrophy. To determine this point Dr. Lange, of Berlin, administered thyroid preparations to several pregnant women under his care, with the result that under this treatment the gland diminished in size, the engorgement reappearing as soon as the treatment was suspended. He infers from this fact that the enlargement is really of the nature of hyperplasia, such hypertrophy being a strictly physiological process. The only possible explanation of this phenomenon is that there exists in the blood of pregnant women a substance or substances peculiar to this state, capable of acting directly upon the thyroid gland.

It must, however, be borne in mind that all pregnant women do not display this tendency to enlargement of the thyroid. Thus of 133 women observed during the last three months of pregnancy, twenty-five did not exhibit any tendency to glandular enlargement, but of these twenty-five no less than eighteen were suffering from albuminuria of pregnancy. As, on the other hand, women suffering from chronic nephritis exhibit this gestation goitre in the usual way, Dr. Lange concludes that the thyroid hypertrophy is more likely to be
absent in women who fall victims to one or other of the renal affections associated with the pregnant state. It is obvious that the non-existence of "gestation goitre" cannot be due merely to the existence of the albuminuria of pregnancy, seeing that the latter makes its appearance, as a rule, much later than the hypertrophy of the gland; and, moreover, it has been shown that Bright's disease by no means interferes with the development of this ephemeral variety of goitre.

Comparative experiments on pregnant cats seem to show that pregnant animals require a larger volume of thyroid gland for the maintenance of health than non-pregnant animals, and when more than four-fifths of the gland is removed the animal develops tetany, which subsides under the administration of thyroid extract. Moreover, in a cat possessed of sufficient thyroid gland to maintain health under ordinary circumstances, the supervision of pregnancy is soon followed by symptoms of more or less pronounced renal disease. Clinical experience, as far as it goes, seems to confirm these experimental data, for Dr. Lange has had under observation two women who during their first pregnancies had albuminuria and no goitre, whereas in subsequent pregnancies they presented this hypertrophy of the thyroid gland and no albuminuria. These facts would seem to warrant the inference that there is a close relationship between the activity of the thyroid gland and that of the kidneys, and it is conceivable that another field of usefulness may be opened out for this protean medication, not only in obstetrics, but also in gynecology, for it is quite possible, though no clinical demonstration thereof is as yet available, that some forms of dysmenorrhea may be dependent upon deficient activity of the thyroid gland, the importance of which in the animal economy has so recently been demonstrated.—Medical Press and Circular, May 3, 1899.

JUSTUS'S TEST FOR THE DIAGNOSIS OF SYPHILIS.

Cabot and Mertins, in the Boston Medical and Surgical Journal of April 6, 1899, record their views concerning this test. In two papers published in 1895 and 1897 respectively a new test for the diagnosis of doubtful cases of syphilis was described by Justus, an assistant in Schwimmer's clinic at Budapest. The test depends upon the sensitiveness of the red blood-corpuscles in syphilitics to the action of mercury exhibited by inunction, or by subcutaneous or intravenous injection. This sensitiveness, which is said by Justus to be greater in syphilis than in any other disease, is shown by a sudden sharp fall in the percentage of hemoglobin during the hours immediately following the administration of the drug. Later the hemoglobin gradually rises to a point above that seen before the injection. Such a sharp fall of ten to twenty per cent in the hemoglobin following the use of mercury was observed by Justus in over 300 cases of syphilis, and the absence of any such fall in non-syphilitic cases was attested by "very numerous" control experiments.

The sign was observed in all untreated cases of the secondary, tertiary, or congenital form of the disease, and in thirteen out of sixteen cases in which only a fresh chancre and inguinal adenitis were present. "Latent cases," so called, showing no lesion, and cases in which the lesions have passed their acme and are subsiding, either spontaneously or under treatment, do not react characteristically to the test. It is therefore in florid cases with advancing lesions of whatever type that the test is positive. This includes relapses of all kinds so long as the lesions are in active condition.

The amount of the fall in hemoglobin after a given dose of mercury depends, according to Justus, on the severity of the disease and the condition of the patient. The same conditions determine how soon the blood shall return to its normal condition.

If a subcutaneous or intravenous injection is given the characteristic sharp fall in hemoglobin usually follows each of the first three or four doses, while if the method of inunction is used the hemoglobin falls only after the first inunction. If the drug is given by mouth no effect on the blood is to be observed. Intravenous injections act so rapidly that within an hour a loss of fifteen per cent of coloring matter has been noted. Microscopic examination of the blood immediately after an intravenous injection of mercury (corrosive sublimate, one to six milligrammes, in from 1000 to 3000 parts of normal salt solution) showed evidences of destruction of red corpuscles, with hemoglobinemia and an increase of urobilin in the urine. This is very transitory, however.

As an example of the value of the test in differential diagnosis, Justus quotes a case of advanced pulmonary tuberculosis in a man who had had syphilis nine years before. An
ulceration of the larynx existed, and experts differed as to whether it was a syphilitic or a tubercular ulcer. Justus's test was negative, and it was confirmed by the results of the autopsy, which showed a tubercular and not a syphilitic process.

Charts indicate the daily changes in the hemoglobin in two typical cases published by Justus. The first chart shows the course of the hemoglobin in a case of syphilis treated by inunctions, the crosses marking the times at which the drug was given. The sharp initial drop followed by a gradual rise is well shown. The second chart shows the effect of intravenous injections of corrosive sublimate (one to six milligrammes, diluted 1000 to 3000 times). Here not only the first administration of the drug but the three succeeding ones are followed by considerable losses in hemoglobin, and it is only after the first injection that a steady rise takes place.

In the summer of 1898, at the out-patient department of the Massachusetts General Hospital, Cabot and his collaborer tried this test in seven cases of undoubted syphilis, four cases suspected of being syphilitic, and thirty-three control cases of various other diseases—a total of forty-four cases. Inunctions were used in all cases, from fifteen to forty grains of the unguement hydrargyri being given to each patient, with directions how to apply it.

The hemoglobin was tested before the inunction, and then twenty-four hours later; the tests being all performed by the same observer with the same instrument and under similar conditions. A change of less than ten per cent was not counted as a positive reaction.

In a general way the results certainly tend to confirm the statements of Justus. All the syphilitic cases reacted strongly and characteristically, and in thirty-three control cases there was but one genuinely positive reaction.

The seven active syphilitic cases lost an average of twenty-one per cent of hemoglobin after one inunction. This is surely not accounted for by errors in technique, and is in very marked contrast with the figures obtained in the control cases. Of these only two out of thirty-three showed any considerable change after the inunctions. Slight gains and slight losses are recorded by all within the limit of error, except two cases. One of these was a case of tertian malaria in which a chill occurred just after the inunction. This is sufficient to account for the loss of ten per cent of hemoglobin. The other was a case of chlorosis; in this a typical positive reaction was obtained with a loss of thirteen per cent in hemoglobin. So far as it goes, this case certainly tends to diminish the value of Justus's test. No evidence of syphilis was present and no history of it.

Results: (1) Positive reactions in seven cases of syphilis; (2) negative reactions in thirty-two control cases of other diseases; (3) positive reaction in one case of chlorosis.

PNEUMATIC MASSAGE IN THE TREATMENT OF DEAFNESS AND TINNITUS.

Webster reports five cases treated by pneumatic massage. They include conditions resulting from chronic suppuration of the middle ear, varying from small perforation to complete destruction of the tympanic membrane. These observations were made on cases where suppuration had ceased and the middle ear was dry. The hearing was markedly improved in all but the first and second. In the first, it is noted, the gain was very slight; in the second, that a slight primary gain was followed by a slight loss. The tinnitus was markedly relieved in the first case; temporary relief only after each treatment in the second; lessened in the third; permanently relieved in the fourth; lessened in the fifth. The cases showing the greatest gain in hearing were those in which suppuration had recently ceased. The case which showed relief of tinnitus permanently was not a recent case. Webster concludes that in the class of cases above mentioned pneumatic massage may be of considerable value in addition to other means of treatment. He was unable to realize any greater benefit from very rapid vibrations than from slow. He therefore sees no advantage to the patient in a motor, but thinks the Siegle speculum with the hand-bulb would do equally well. The rapid vibrations were attended with some noise, which was at times disagreeable to the patient.

PERCUSSION OF THE CRANIIUM.

Gille de la Tourette and Chipault (La France Médicale, No. 13, 1899), recognizing the fact that the thickness of the skull of the normal individual, though it has been carefully studied out, is of little service as a guide to the surgeon in individual cases of disease, have endeavored to provide a
reliable means of determining this matter by percussion. They employ either a small mallet, or, preferably, the finger; the latter conveys the sense of elasticity and of resistance, which after practice can be justly interpreted. This percussion should be practiced with the mouth of the subject closed. The percussion note is resonant in the child; dull in the adult, especially in the male; less dull in the aged. It is more resonant in the frontal and parietal regions than about the occiput. The authors report five cases which they believe show the value of percussion. The first was trephined because of mental symptoms following trauma; the note over the entire frontal region was dull, as compared with the note elicited from the normal heads of the attending surgeons. The frontal bone was found on operation to be greatly thickened and dense in structure. One case of trephining practiced for the removal of a neoplasm, which was not found, gave a clear percussion note; the skull was extremely thin. One trephining practiced for old trauma gave a normal percussion note, and the skull was of normal thickness. The other cases were equally satisfactory to the authors, who announce that the resonance of the cranial region varies according to the thickness of the bone, being greatest when the bone is thinnest, and inversely. They also detected a "cracked-pot" sound in the case of old fracture, and express the hope that this may be a valuable means of diagnosing fractures of the skull which are accompanied by no other pathognomonic symptom.

---

**A METHOD FOR THE REDUCTION OF DISLOCATION OF THE HIP.**

Sturrock (British Medical Journal, April 8, 1899) thus describes a method of reducing dislocation of the hip: The patient, being laid upon his back on the floor, is put under the influence of an anesthetic. The surgeon kneels upon his left knee when the left hip is dislocated, and on the left side of the patient. The patient's thigh is then carefully flexed to a right angle, and while this is being done the leg is also flexed to a right angle, and laid with the most prominent part of the calf on the right knee of the surgeon. The ankle is then firmly grasped with the left hand, and the condyles of the femur with the right. The thigh is then abducted for thyroid dislocations, adducted for dorsal and pubic, and rotated in for all, by drawing the foot away from the middle line and keeping the knee steady. Traction is now made by steadily depressing the ankle, the surgeon using his knee as the fulcrum; the patient's leg makes a most powerful lever, and the pelvis can be easily raised off the ground if necessary, the weight of the body acting as counter-traction; then finally the thigh is rotated out, and while this is being done the head of the femur slips into the acetabulum.

---

**WOUNDS OF THE PERITONEAL PORTION OF THE RECTUM.**

Quenu (Revue de Chirurgie, January, 1899) points out that in cases of wound of the rectum it is very important with regard to prognosis and treatment to determine as soon as possible whether the abdominal cavity has or has not been penetrated. To a collection of thirty-five previously recorded cases of penetrating wound of the peritoneal portion of the rectum, this surgeon adds one under his own care in which laparotomy was performed with good results. Notwithstanding the facilities afforded by the use of the rectoscope in exploration of the rectum, it is very difficult to make out whether the wound has penetrated or not, especially if the examination be made soon after the receipt of the injury, and before there are any indications of abdominal mischief. The author advocates laparotomy both in cases in which there can be no doubt as to penetration, and also in doubtful cases in which there are some signs of commencing peritonitis. In six of the thirty-six collected cases laparotomy was performed four times with success, twice with fatal results, the mortality being thus 33.3 per cent. Of twenty-nine patients on whom laparotomy was not performed, twenty-four died, the mortality being eighty-two per cent.

In describing the details of his treatment of a wound extending from the rectum into the peritoneal cavity, the author insists on the importance of prompt laparotomy, of elevation of the patient's pelvis during the operation on an inclined table, of free exposure of the interior of the pelvis by upward displacement of the small intestines, of careful examination of the bladder and sigmoid flexure, which might also be involved in the injury, and of prolonged and thorough cleansing of the abdominal lining and contents by warm artificial serum. The duration of the operation and the chief difficulty will, as a rule, vary according to the seat of
the penetrating wound. Whilst such a wound of the sigmoid flexure may be readily and speedily closed by a double row of sutures, it will be found a very laborious task to reach and close an opening situated at the bottom of the rectovesical pouch. Much of this difficulty, it is thought, might be overcome by elevation of the anterior wall of the rectum by means of a carefully distended elastic bag.

**THE TREATMENT OF FAVUS.**

**Von Peterson** (Berliner Klinische Wochenschrift, No. 15, 1899) applies a two-per-cent carbolic acid ointment to the scabs three times a day until they are softened and removed. The diseased area is then painted every second or third day with iodine tincture. Epilation is not always necessary. A cure may require a ten months' course of treatment.

**HERPES AS A FORERUNNER OF CHANCREE.**

**Andery** (Berliner Klinische Wochenschrift, No. 15, 1899) has noted in a number of cases preputial herpes preceding the development of a chancree, and regards the outbreak of an eruption of this kind in a young man who has been exposed to the disease as highly suggestive of syphilitic infection.

**THE TREATMENT OF PROSTATORRHEA BY PROSTATIC SUBSTANCE.**

**Oppenheimer** (Berliner Klinische Wochenschrift, No. 15, 1899), led thereto by the published reports of the excellent results of organotherapy, has been administering prostatic substance to patients suffering from non-gonorrheal prostatorrhea. He notes as a result a rapid and permanent cure. The treatment is contraindicated by the presence of the gonococci. The dosage and method of preparation are not mentioned.

**THE OPERATIVE TREATMENT OF VARICOSE VEINS.**

**Pierce Gould** (The Lancet, April 8, 1899) reports fifty cases of Trendelenburg's operation for varicose veins. It will be remembered that this operation consists in excision between double ligatures of a short piece of the internal saphena vein in the thigh, the object of this procedure being to protect the varices from the pressure and reflux of blood from the common femoral vein and venous trunks above it.

In any attempt to appreciate the value of this operation, an account of its immediate results up to the time the patient leaves the surgeon's hands is of no value. It is all-important to learn the later history of the patient. This Gould has been able to do in thirty-nine out of the fifty cases, and personally has seen twenty-five of them. In no single instance did the operation fail to relieve the patient of all pain, and it was invariably followed by a marked, often a very marked, shrinking of the dilated veins, sometimes to quite their normal size, in others to just short of that. This shrinkage may progress for many months. In no case did thrombosis develop above the ligature. The patients are usually kept in bed but a week.

One of the most troublesome complications of varicose veins is aseptic thrombosis; it is sometimes very painful, and is not free from danger to life from embolism, and the course of the disease under the common palliative treatment is often exceedingly slow and not infrequently followed by relapse. Under these circumstances it is reasonable to try whether surgery does not afford a better means of dealing with these cases than the older methods of rest, local sedatives, moderate diet, alkalines, salines, and great patience. Thus Gould has treated two cases of aseptic thrombosis by excision of the thrombosed portion of the vein and immediate closure of the wound. Union by first intention was obtained.

**EXPLORATORY OPERATIONS UPON THE STOMACH FOR OBSCURE AND OBSTINATE GASTRIC SYMPTOMS.**

Under this title **Maylard** (The Lancet, April 8, 1899) holds that there should be less hesitation than is at present exhibited in opening the peritoneum and subjecting the stomach to a thorough manual exploration in cases characterized by obstinate gastric symptoms. He quotes Kocher to the effect that he has regretted delay in operating often; operating, never. A reference is made to two cases—one reported by Bradford, the other by Treves—in which, though nothing definite was found, yet immediately a marked relief was obtained in each case. Robson, acting on lines somewhat similar, discovered by exploratory laparotomy that certain obscure gastric symptoms were due to adhesions involving some part of the external gastric apparatus, the separation of which resulted
in complete relief. He also showed that exploratory gastric operations have been the means of revealing obstruction at the pylorus as the cause of dilated stomach, and that the treatment of this obstruction has led to the disappearance of all symptoms of tetany from which the patient had suffered.

As a case in point, Maylard quotes the following experience: The patient, fifty-five years old, three years before he came under observation began to suffer from pain in his back, which soon shifted to the epigastrium, where it remained continuously. It was burning and gnawing in character, and located just below the ensiform cartilage. It was somewhat aggravated by hunger, and was frequently relieved by the ingestion of food. He never vomited, but was flatulent. There was pain on pressure over the affected area, and the stomach was apparently dilated. There was also a mitral murmur. No improvement followed medical treatment and fasting. Laparotomy was performed; the stomach was freely withdrawn through the parietal wound, and its anterior wall was incised. Nothing abnormal could be found. The opening in the stomach was then closed, and the anterior wall was tucked in and secured by sutures for the purpose of lessening the dilatation. The next day the patient vomited two and a half pints of pure blood. The wound was reopened, and a small bleeding vein was found at the margin of the incision. Three pints of hot normal saline solution was injected into the median cephalic vein; the stomach was freely washed out, much blood-clot being thus removed.

The patient completely recovered, gaining weight, and remaining free of his pain.

**CONTRAINDICATIONS TO PARACENTESIS IN SEROFIBRINOUS TUBERCULOUS PLEURISY.**

Mollard (Lyon Médical, No. 15, 1899) strongly argues against paracentesis for relief of serofibrinous pleural effusion which is slow in being absorbed, unless the pressure exerted by such an effusion is immediately threatening to life. He states that clinical experience, pathological anatomy, bacteriology, all teach that intervention under such circumstances directly interferes with nature's method of accomplishing a cure. Moreover, by tearing the new membrane which has been formed, and by wounding blood-vessels and lymphatics, it opens the entire system to infection. The serum has a distinct inhibiting effect upon the bacilli, and the false membrane formed serves to limit them until their toxic and multiplying powers have been destroyed. When this has been accomplished, in the vast majority of cases the serous effusion will be absorbed.

**THE PRESENT POSITION OF THE PESSARY IN GYNECOLOGICAL PRACTICE.**

Ballantyne (Scottish Medical and Surgical Journal, April, 1899) thus sums up the advantages of the pessary in gynecology:

1. All the strong supporters of treatment by pessaries emphasize their convenience. An occasional visit to a gynecologist, occupying probably only a few minutes, frequent vaginal douching, which possibly would be required anyhow, a transitory feeling of uneasiness in the pelvis when the pessary does not exactly fit or has been worn rather too long, cannot surely be regarded as sufficient reasons for advising a patient to face the ordeal of a plastic operation with all its inconvenience, its expense, and its enforced confinement to bed for a longer or shorter time. As Mundé puts it, "Not every patient who has a displacement of the uterus wishes to be operated upon for its permanent cure."

Further, there are the cases in which it is impossible for the patient, either on account of her advanced age or her occupation, to have any operation at all; in such instances the pessary becomes a great convenience.

2. The opinion of all who make use of pessaries in their gynecological practice is that they are undoubtedly effective in relieving symptoms. Some go further and state that they in many cases produce a permanent cure in a longer or shorter time. Mundé, speaking of recent displacements, affirms that in about twelve cases in a thousand the pessary may in a year or two be no longer needed. He says further: "No tampons, no astringents, no massage, no electricity, no posture, no baths, no vaginal douches, will, in my experience, take the place of a properly fitted vaginal pessary."

Herman, writing on prolapse, says that "if a vaginal pessary is retained and keeps up the uterus, relief is almost complete and greater than can be obtained in any other way;" and in referring to chronic retroflexion, he believes that only about one case in fifty calls for any other methods of treatment than that by pessaries. Lewers goes further than most of the advocates of the preferential treatment of displacements by pessaries, for he affirms
in relation to prolapse that "no plastic operation will cure cases of procidentia; no matter how complete the success of the operation may appear at the time, unless the patient wears a pessary the displacement will most probably return as badly as ever. If, however, she wears a ring, a permanent condition of comfort is obtained." Macnaughton-Jones has no doubt as to the efficiency of the well adjusted pessary, for he asserts that "in all forms of displacement where its employment is clearly indicated, it generally gives material relief." The advocates of pessaries may differ in their views as to the manner in which these instruments relieve symptoms, but that they do relieve symptoms all are agreed. That they are an effective means of treating displacements is, therefore, urged as their great advantage.

3. Most gynecologists freely admit that the ordinary vaginal pessaries used with ordinary care are perfectly safe; but those who strongly advocate their use claim that even intra-uterine stems and instruments of the Zwanck type are quite innocuous. The bad results that are occasionally reported are ascribed by these pessary partisans to want of care in adapting the pessary to the person, and to absence of precautions on the part of the patient in wearing it. Several writers state that pessaries of the nature of the Zwanck type must be taken out every night by the woman herself and replaced in the morning, and they do not apparently fear that she may be unable or unwilling to do so, nor do they dread any evil results from her want of knowledge of the anatomy of the parts. All these authors emphasize the safety of the pessary as contrasted with the danger of other, and especially of surgical, methods of treating displacements; and to them the remark made by Lawson Tait that he is certain that removal of the ovaries is "a far safer proceeding than the employment of intra-uterine stems, and has the merit of being effectual," must appear extraordinary indeed.

The alternative kinds of treatment in incomplete prolapse, with a certain degree of perineal efficiency, may be stated to be: (1) The purely palliative plugging of the vaginal vault with glycerin or ichthyol tampons, with or without rest and douching; (2) uterine curettage to diminish the uterine subinvolution and restore tone; (3) anterior colporrhaphy, especially when there is marked cystocele; (4) perineorrhaphy even when the perineum is not markedly defective; (5) ven- trofixation of the uterus (not often); and (6) Alexander's operation (not often).

In cases of complete prolapse, where the perineum has almost or entirely lost its power of retaining a pessary in the vagina, the only form of support which is possible is the stem, with an abdominal belt and outside straps and perineal pad. The only cases in which most gynecologists would countenance the wearing of such supports are in old women who either refuse or who are too weak to be subjected to operative procedures, or in younger women who absolutely decline to be relieved in any other way. The most hopeful view that one can take of treatment by pessaries in these cases is that by their means a complete prolapse is turned into an incomplete one, and that in time it may be possible to replace the stem and outside straps by a single vaginal pessary. The alternative procedures to pessaries in the treatment of complete prolapse are: (1) perineorrhaphy; (2) colporrhaphy, anterior or posterior, or both, with or without perineorrhaphy; (3) ventrofixation of the uterus; (4) Alexander's operation; and (5) vaginal hysterectomy.

Most authors are now agreed that to try to treat anteversion of the uterus by pessaries is to use means which are inadequate to remedy a condition which is not itself productive of trouble. If, however, an enlarged, chronically inflamed uterus is more or less fixed in an antverted position, then symptoms arise which are due immediately to the metritis. Consequently most gynecologists treat the metritis and the metritis only, and in doing so do not invoke the help of pessaries; but some think that the insertion of an indifferent pessary, such as the ring, is of value in hastening the cure by raising the uterus.

Most authorities are now agreed that a congenitally fixed and flexed uterus is not amenable to treatment by pessaries. Another point about which there seems to be general agreement is that no vaginal pessary will straighten an anteflexed uterus even when the uterus is fairly movable. The question in anteflexion and its treatment by pessaries has therefore narrowed itself down to the justifiability of employing intra-uterine stem pessaries. Even strong advocates of treatment by mechanical supports are in doubt whether the risks attendant upon wearing intra-uterine stems do not more than counterbalance any good effects which may arise therefrom. Various devices have been adopted to render intra-uterine stems innocuous, and
while it cannot be said that any one has succeeded, it may be admitted that the entire intra-uterine (i.e., without a vaginal portion) pessary recently brought forward by Lefour comes nearest the standard. It has been not infrequently claimed by the advocates of intra-uterine stems that menstruation, scanty and accompanied by great pain before the introduction of the stem, becomes profuse and painless after it has been placed in the uterus; but opponents of the stem point out that the pessary in such cases, instead of draining away discharge, has really produced the discharge by setting up suppuration, and has led to lesions that take months to heal.

While pessaries are coming to be looked upon as unnecessary and ineffective in antecedents, and as temporary and palliative props in prolapus, it is evident that the mind of the profession is far from made up on the question of their use in retroversions of the uterus. J. C. Webster divides cases of retroversion into seven classes and gives special directions for the management of each.

In retroversion with a uterus fixed by peritonitic adhesions no pessary is to be used.

In retroversion with a freely movable uterus, not enlarged, and with no pelvic trouble, there is no necessity for reposition and the pessary, but if there is bronchitis or the lifting of weights, then it is well to keep the uterus antverted by a pessary.

In retroversion of a freely movable uterine with no pelvic trouble, there is no need for a pessary, but if there are to be strains and lifting weights, then use a Hodge or Smith pessary.

In retroversion of the pregnant uterus use a Hodge or Smith up till the fourth month.

In retroversion with a movable uterus, with pelvic symptoms, but with neither ovary in the pouch of Douglas, use the Hodge or Smith.

In retroversion of a movable uterus with pelvic symptoms, and with one or both ovaries in the pouch of Douglas, use no pessary till the ovarian inflammation has been diminished by douching and plugging, then use first the ring, and afterwards the soft Hodge or Smith or Thomas.

In retroversion of a movable uterus with pelvic symptoms and old posterior perimetritis or cellulitis, follow much the same lines as those in the preceding rule.

**SENILE ENDOMETRITIS.**

**LORAIN (Annals of Gynecology and Pediatry, May, 1899; quoted from La Revue Médicale)**

states that this disease is comparatively rare, forming a little over seven per cent of all cases of endometritis. One of the first symptoms of senile endometritis is a semipurulent yellow or greenish discharge, often streaked with blood, and occasionally offensive; the discharge is sometimes continuous, sometimes intermittent. Metrorrhagia is not rare, and is occasionally so marked as to give rise to what is described as the hemorrhagic form of the disease; the loss of blood is, however, rarely great, and never by itself constitutes a grave symptom.

The disease is usually but slightly painful, the subjective symptoms being limited to a feeling of weight in the hypogastrum and to sacralgia.

Sometimes, however, the patient complains of smarting and itching about the vulva; in most cases this is due to the irritation of the discharge, but occasionally no signs of inflammation are present. Frequency of micturition and pain after the act are sometimes observed.

There is little tendency for the inflammation to spread to the Fallopian tubes, but it does occasionally take place. Perimetritis and parametritis are practically never found.

The uterus is usually found to be of normal size, mobile, but slightly tender; the speculum reveals a cervix more or less inflamed, of a deep-red color, swollen, and smooth. Cervical erosion is rare.

The course of the disease is essentially a chronic one; the symptoms become more marked after exertion and fatigue; but the acute or subacute exacerbations found in endometritis anterior to the menopause, and probably due to menstrual congestion, are not found in senile endometritis.

The general condition of the patient is always to some extent affected by the disease; loss of flesh, anemia, dyspeptic troubles, occasionally rigors and night sweats, and, in fact, a condition of cachexia more or less marked, are found.

The diagnosis of senile endometritis is of the greatest importance, owing to the resemblance its symptoms bear to those of cancer of the body of the uterus. The treatment depends essentially on an accurate differential diagnosis. If the disease is merely endometritis, medical treatment will always guarantee a cure. On the other hand, if the disease is cancer of the body, hysterectomy, at least in the early stages, is the only rational treatment, and the prognosis becomes grave, not only by reason of the dangers of
the operation itself, but also because of the grave risk of a recurrence of the disease.

Treatment should have two ends in view: (1) To allow of the free escape of the secretions of the uterine mucous membrane; (2) the application of antiseptics to the interior of the uterus.

The free escape of the contents of the uterus is of special importance, since, as long as these are pent up in its cavity, no cure can be expected. Generally speaking, the dilatation of the cervical canal is best effected by Hegar's dilators; but cases arise in which the stenosis of the cervical canal is so advanced that the smallest dilator cannot be introduced; in such cases dilatation must be obtained with laminaria tents. It is generally sufficient when the passage of Hegar's No. 7 or No. 8 can be effected, but this will often require two or three sittings at intervals of twenty-four or forty-eight hours. After dilatation, one of the following solutions should be applied to the cavity of the uterus:

- Cresote,
- Glycerin,
- Alcohol, equal parts of each.

Or,

- Ichthyol, 10 parts;
- Glycerin, 40 parts.

Or,

- Pure tincture of iodine.

These are introduced into the uterus by means of a flexible sound, the last two inches of which is surrounded by cotton-wool; this is then soaked in the solution and applied to the whole surface of the uterine mucous membrane.

The treatment should be renewed two or three times a week, and in the intervals a drain of antiseptic gauze should be left in the uterus, a tampon of similar gauze being left in the vagina.

As the cervical canal tends to contract again between the dressings, it will be found necessary to further dilate it from time to time.

The duration of treatment carried out according to the above principles will be found to be approximately from three to four weeks.

**TOXIC INFLUENCE OF CHLOROFORM.**

Schenk (Centralblatt f. Chirurgie, No. 19, 1899; quoted from Zeitschrift f. Heilkunde) reports the case of a woman subjected to a half-hour's narcosis for extirpation of the uterus, an ovarian cyst, and a right-sided pyosalpinx, who three days afterwards died of cardiac failure and renal affections. Section showed a well-marked fatty degeneration of the heart, liver, and kidneys. The author ascribes this degeneration to the action of the chloroform upon organs previously weakened by septic fever. These findings correspond to those frequently observed in patients who die a few days after the administration of chloroform. Schenk conducted an experimental investigation upon monkeys and dogs for the purpose of finding out how soon after narcosis fatty degeneration became demonstrable in the organs, and when it disappeared and there was a return to the normal. He came to the conclusion that the fat which appeared a few days after chloroform narcosis did not disappear for days or even weeks; that even after ether narcosis fatty degeneration was to be noted in the liver, although it was less marked than when chloroform had been used. Therefore, he warns against the use of chloroform excepting when it is absolutely necessary, and especially he objects to the practice common in gynecological clinics of narcotizing individual patients frequently, at short intervals, for the purpose of establishing a positive diagnosis. It is obvious that if a single chloroformization causes a moderate degree of fatty degeneration which persists for some time, a second anesthetization may increase this change to a dangerous degree.

**THE TREATMENT OF TUBERCULOSIS OF THE TESTICLE.**

Berger (Journal des Praticiens, No. 16, 1899) states that castration should be employed in beginning tuberculosis when the lesions are rapidly progressing and unilateral; that involvement of the deferent canal and even the seminal vesicle is not a contraindication to the operation; that this procedure should be completed by extirpation of the entire deferent canal even when this seems perfectly healthy. If the seminal vesicle participates in the tuberculous degeneration, it can be extirpated either by the inguinal route, or better still, by the perineal incision. In all cases where a tuberculous testicle is one of the principal causes of alteration in the general health, of pain, or of general weakness, even though there exist tuberculous lesions in other parts of the body, castration should be performed—not, however, if both testicles are involved.
CAESARIAN SECTION BY MEANS OF A TRANSVERSE INCISION OF THE FUNDUS.

Thumin (Centralblatt f. Gynaekologie, No. 19, 1899) reports a case of Cesarian section in which after exposure of the uterus its cavity was opened by a transverse incision, carried across the fundus from the insertion of one tube to that of the tube of the opposite side. The delivery of the child with the placenta, he states, is extremely easy, and the bleeding from the incision very slight. After contraction of the uterus the wound became, as Fritsch states, surprisingly small. Silk sutures carried through the entire thickness of the uterine wall, and a serous membrane suture of very fine thread, completely closed this wound. Braitenberg has collected fifteen cases in which this transverse incision was employed, and reports the sixteenth himself. The chief advantages claimed for this incision are that it spares the lower uterine segment, and that it enables the fetus more readily to be delivered.

OLD DISLOCATIONS OF THE SHOULDER.

Duplay (Le Progrès Médicale, March 4, 1899; quoted from the Montreal Medical Journal, May, 1899) deals especially with old dislocations. How are they to be treated? He would classify those of six weeks' standing as old. In recent dislocations the difficulties occasionally experienced in effecting reduction are numerous. The head of the humerus may have traversed an intermuscular space. More frequently the ligament offers an opposition almost impossible to overcome, or the capsule may be in the way of the return of the head. If the great tuberosity is torn off the difficulties are still greater.

In old dislocations the difficulties arise from changes in the muscles, ligaments, and bones.

The anterior part of the capsule retracts and the posterior part covering the glenoid cavity forms adhesions with it which oppose the replacement of the head. The tuberosity when torn off may lie against the glenoid, become engaged in callus, and thus form an obstruction. Again, a new pseudocapsule gradually forms. Malgaigne has drawn attention to the formation of fibrous bands adherent sometimes to the vessels; and the result of tearing these vessels by violent manipulation is easily understood.

The muscles become displaced and form adhesions in their new situation, and the long head of the biceps is especially mentioned as obstructing in this way.

The glenoid contracts and may form a part of the new articular cavity. The head of the humerus becomes altered in shape and occasionally gives origin to bony overgrowth.

The ideal treatment is to effect reduction, as in recent cases. Unfortunately, this is often impossible. Kocher has frequently succeeded by his method after the lapse of three or four months, although dislocations eight years old are said to have been reduced by manipulations. Failing reduction by manipulation, M. Duplay recommends incision and reduction after loosening the head of the bone, providing it can be done without too great a division of muscles and adhesions. Otherwise a resection of the head of the bone gives a very good result.

VACCINATION FOR HYDROPHOBIA AT LILLE.

From the 12th of February, 1895, to the 1st of January, 1899, 796 persons who had been bitten were treated at the Pasteur Institute at Lille. Two hundred and thirty-three were bitten by animals in which the presence of hydrophobia was proven by inoculation; 325 were bitten by animals in which hydrophobia was diagnosed by veterinary surgeons; finally, 234 were bitten by animals in which hydrophobia was simply suspected. The average length of the treatment was eighteen days. Five people died of hydrophobia in spite of the treatment, giving a total mortality of 0.62 per cent. There were 771 dog-bites, 22 cat-bites, 2 horse-bites, and 1 ass-bite.—Lyon Medical, No. 18, 1899.

THE TREATMENT OF HEMORRHOIDS.

Schwartz (Journal des Praticiens, No. 16, 1899) states that the indications for operation in cases of hemorrhoids are: bleeding, pain, an abundant mucous discharge, habitual procidentia, and ulceration. Operation is not advisable when the hemorrhoids are painless and uncomplicated, and when they are symptomatic of lesions of the pelvis or viscera. Moreover, when they are accompanied by regular bleeding, and occur in gouty patients without apparently influencing the general health, the general treatment so well known is advised. As to the operative treatment, the value of dilatation
THE THERAPEUTIC GAZETTE.

is again insisted upon. Cauterization is considered par excellence the best method. Each small tumor is seized in forceps and cut away with a hot iron. This, it is stated, can be done painlessly after first freezing the mass which has been seized, by chloride of ethyl. The iron should be heated only to a dull red, as otherwise it will set fire to the ethyl vapor.

RECTAL INJECTIONS OF SALINE SOLUTIONS IN THE TREATMENT OF HEMORRHAGE, SHOCK, AND INFECTIONS.

LÉpine (Lyon Médical, No. 18, 1899) closes a thesis on this subject with the following conclusions: There are two classes of phenomena dependent upon such injections. The first are physical or chemical, and correspond to those incident to blood transfusion, or the transfusion of artificial serum. The second are purely physiological and are not clearly understood. Intravenous and subcutaneous injections are not absolutely free of danger, and are somewhat difficult of application. Absorption of the saline solutions by the rectal mucous membrane is as easy and rapid as that which takes place when the solutions are injected beneath the skin. The therapeutic effect of the rectal injections is precisely the same as that of subcutaneous injections. The strength of the solution varies according to the indications.

THE PREVENTION OF POSTOPERATIVE THROMBOSIS IN VEINS OF THE LOWER EXTREMITY.

Lennander (Centralblatt für Chirurgie, No. 19, 1899), in commenting upon the frequency of the so-called milk-leg after all abdominal operations, states that he has had this complication occur in five cases of appendicitis operated on in the interval between the attacks. He notes that it is very commonly observed after all abdominal operations and after herniotomy, even when the wounds run a perfectly aseptic course, developing not infrequently two or three weeks from the day of operation. Thinking that perhaps compression exerted upon the femoral or long saphenous vein, due to the abdominal bandage, might have caused this complication, in some of these cases Lennander so placed his dressings that such pressure could not possibly be exerted, yet in spite of this thrombosis developed, sometimes involving not only the long saphenous and the femoral veins, but even the external iliac.

In view of the long confinement to bed necessitated by this complication, of the often permanent partial disability, and of the serious danger to life from secondary pulmonary embolus, a careful study was made as to the means by which this complication might be prevented. As to its cause, there can be little doubt that suppuration in or about the wound is a predisposing factor—not, however, a necessary one, since the complication develops after operations which run an absolutely sterile course. Toxemia, of intestinal origin, is no doubt a predisposing factor, yet the direct relation in individual cases often cannot be traced. Ziegler states that the two causes of thrombosis are a slowing of the circulation, and local alterations in the walls of the blood-vessels. Slowing of the circulation is often due to weakness in the heart's action, a common accompaniment of abdominal diseases requiring operation. It is further accentuated by meteorism, which materially interferes with the aspirating influence exerted by the normal chest upon the venous circulation. Local alteration of the blood-vessels, such as endophlebitis and fatty degeneration of the endothelium, is often primary and of local origin; often secondary to infection, or autotoxic alterations of the blood. The primary degenerations are noted in patients who suffer from varices, or those who before operation have suffered from slight thrombosis.

Lennander noted in his series of cases that the milk-leg was seldom observed after the extremely severe and complicated laparotomies, and explains this circumstance by the fact that the after-treatment of these cases was conducted with the lower end of the bed elevated ten to twenty inches, and that into the abdominal cavity of these patients there was often injected a pint to a quart of normal salt solution. On a basis of these observations, about the middle of 1897 he adopted, as a general practice after every abdominal or hernial operation, the elevation of the foot of the bed to a height of from four to twenty inches. Patients who were healthy before operation were subjected to moderate elevation; those who had been exhausted by previous disease, who were anemic, or had previously suffered from varices, were subjected to the highest elevation. If the position became unbearable, the foot of the bed was somewhat lowered, but never to a level less than four to six inches. It was kept in this position during the entire stay of the
patient in the hospital. When the blood-pressure was low, and the heart action weak or irregular, subcutaneous injections of normal saline were given, together with the usual stimulating heart tonics. Especial care was taken that the bandage did not press upon the crural vein, and very shortly after operation passive movements and light massage of the foot and leg were practiced. The patients were then instructed to move their legs as soon as practicable. In many cases, especially those suffering from varices, an elastic bandage was applied to the legs.

Since the period when this treatment was adopted the author had but a single case of thrombosis. A young, apparently strong student was operated on because of chronic appendicitis. The wound healed promptly and without suppuration. After about two weeks thrombosis began in the right leg; it extended upward and completely blocked the femoral vein. This was the only case in which the foot of the bed had not been elevated. The author therefore holds that by elevation of the foot of the bed this troublesome complication can in nearly all cases be prevented. He recommends this same measure in the treatment of many medical affections in which, because of long confinement to bed and the absorption of toxins, there develops anemia, and blood alterations which predispose to thrombus. Thus in typhoid fever, chronic enterocolitis, and chronic peritonitis, this measure is suggested even when thrombosis has begun. Elevation of the foot of the bed is advisable, since thus the return venous circulation is hastened and extension of the thrombus is limited, as it is well known that in circulating blood the fibrin ferment is quickly destroyed.

SUBCONJUNCTIVAL INJECTIONS IN CORNEAL ANDiritic INFLAMMATIONS.

Smyth (Louisville Journal of Surgery and Medicine, May, 1899) notes that while six or seven years ago subconjunctival injections were recommended in almost every disease of the globe or its contents by many of the world’s foremost ophthalmologists, there followed a reaction which condemned the method even for the conditions in which it is most useful. These injections have, however, at present found their true position in ophthalmic therapeutics, and stand as of undoubted value in chronic and relapsing infiltrative disease of the cornea, iris, and ciliary body. Subconjunctivally injected fluids, such as weak sublimate or salt solutions, produce increased lymphatic circulation in the eye, thus causing absorption of pathological products. The latest experiments in this line by Mellinger were to inject an emulsion of India ink into the anterior chambers of a rabbit, and then to inject subconjunctivally salt solution of variable strengths up to a ten-per-cent solution. He states that after six injections, preferably of the stronger solutions, the India ink had been almost entirely absorbed; while in the eye left to itself there was practically no change. The explanation of this result has been given thus: Certain crystalline substances, among which chloride of sodium stands first, withdraw water from the tissues in proportion to their molecular composition, and to the strength of the solution. If the solution is introduced beneath the conjunctiva, it enters the lymph spaces of the eye and tends to extract an excess of fluid from that organ. Thus is induced a more active elimination of the elements of decomposition, necessarily bringing about a more active supply of new nutritive substances from the blood, which naturally results in a more rapid reformation of the changed tissues. This action of the solution is stronger in diseased than in normal tissues.

As to the practical results, Sneller recommends these injections in scleritis; Van Moll in sclerokeratitis and parenchymatous keratitis; and Deutschmann has reported two thousand separate injections, with the conclusion that he has seen better results in parenchymatous keratitis from this than from any other method. The author quotes some illustrative cases of his own.

THE OPEN METHOD OF ADMINISTERING NITROUS OXIDE.

In an editorial upon this topic (New York Medical Journal, May 13, 1899) the method of administering nitrous oxide described by Dr. Flux at a meeting of the Society of Anesthetists in London is favorably commented upon. Dr. Flux discards the closed mouth-piece and uses an inhaler closely fitting the patient’s face, but wide open at the top, into which the gas is allowed to fall from any simple delivery apparatus. The gas naturally falls by its own weight and has no tendency to escape upward, while the accurate adaptation of the inhaler to the face prevents its leakage downward.

By this method of administration, which
Dr. Flux had employed three hundred and fifty times, he affirms that the patient experiences absolutely no discomfort, since he is subjected neither to breathing into an air-excluding face-piece nor to the high pressure at which the gas issues from the cylinder into the inhaler. It is inhaled comfortably at the ordinary atmospheric pressure. Free access of air to the patient is obtained, and the gas is admitted into the inspired air in place of the air being admitted to the inspired gas, as is the case in the ordinary closed method. The gas only needs to be allowed to flow during inspiration, and when once anesthesia has been induced, it can be kept up indefinitely by allowing the patient an occasional breath of gas. Moreover, as the anesthetist has the gas under complete control, he can raise and lower the degree of anesthesia as often and as quickly as desired.

Dr. Flux has had two forms of inhaler made out of clear, thin celluloid, which is light, transparent, pliable, non-absorbent, and easily cleansed. One form is in the shape of a cone open at both ends, for use on patients in the recumbent posture; the other is open at the top and on one side for a patient sitting down. A rubber tube capable of inflation round the face aperture insures accurate adaptation in either form.

From seven to eight gallons of gas is required to induce anesthesia in an adult, and from three to four gallons is required for each additional minute during which anesthesia is to be maintained.

Dr. Flux thus describes the effect of this method of administration upon the patient: "No excitement, stertor, lividity, or convulsive movement, or any sign of asphyxia, occurs throughout the administration and resulting anesthesia—in fact, the whole proceeding is characterized by extreme placidity. In no case has it been necessary to use force to restrain the patient either during or after the exhibition of the anesthetic. Even when administering with unsuitable or improvised inhalers, or under adverse or previously untried conditions, the results have been almost uniformly satisfactory."

In the discussion which ensued, Mr. Baldwin and Mr. Carter Braine, both of whom had seen Dr. Flux administer gas by this method, and the latter of whom had had it tried upon himself, bore testimony to the efficiency of the method. The latter gentleman stated that so insensible was the change when he saw Dr. Flux administer the gas to patients for operation at the Dental Hospital of London, that although he watched the patients very carefully, he was unable to tell when they were anesthetized. They appeared simply to drop off into a normal sleep. For himself, he had taken gas many times, but never so comfortably as in this instance. He breathed perfectly naturally, and did not seem to be taking gas.

_A NEW METHOD OF REDUCTION IN SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR._

Hutchinson and Barnard (The Lancet, May 13, 1899), in December of last year, read a paper upon the above subject, the main contention of which was the value of full flexion of the knee in effecting reduction, and reported three added cases of this injury, with skiagraph pictures showing how completely reduction is effected by this position. Of the sixteen cases of which they have personal knowledge, not less than seven occurred through hanging on behind carts, and the leg becoming entangled in the wheel; in four the separated epiphysis was a part of the general smash due to a lift or railway accident; in three it was due to direct violence, such as the passage of a wheel over the knee; in one it was due to placing the leg up to the knee in the gap between the shafts and the cart and then falling forward; whilst in the last case the injury was inflicted while playing a game well known to schoolboys, in which one boy bends down, supporting himself against a wall, whilst the others leap upon his back and endeavor to break him down. The patient while supporting three boys upon his back was struck upon the knee by the fourth, when his knee gave way, bending backward. Forcible hyperextension of the knee is thus nearly always the cause, and hence if displacement occurs, it is as constantly a forward one of the epiphysis.

The difficulty experienced in trying to replace the epiphysis by direct pressure upon it whilst traction is made in the length of the limb is explained as follows: The stripped-up periosteum is attached to the anterior edge of the epiphysis. The posterior ligament, the lateral ligament, and the crucial ligament, with the two heads of the gastrocnemius, are attached to the posterior half of the epiphysis and behind its axis of rotation. After the epiphysis is torn off, if traction be made in the line of the limb, the epiphysis being attached by periosteum in front and pulled on by ligaments and muscles
behind will rotate on its axis so as to turn its articular surfaces directly forwards, and this is a position in which no amount of direct pressure will replace the epiphysis upon the end of the diaphysis. It is equally clear that if the direction of traction be gradually inclined backwards until the pull is at last at right angles to the axis of the shafts of the femur, the epiphysis will be drawn across the fractured surface of the diaphysis by the pull of the ligaments attached to its posterior half until the band of periosteum attached to its anterior edge checks this backward movement by coming in contact with the anterior surface of the femur.

A method of reduction was devised to make the epiphysis retrace its step backwards, to apply the separated periosteum to the anterior surface of the femur, to withdraw the end of the diaphysis from the popliteal space; and when these objects have been attained, so to fix the limb that the displacement could not recur. The method is as follows: Under complete anesthesia an assistant makes steady but strong traction upon the tibia in the line of the limb. This overcomes the upward pull of the quadriceps extensor and brings the epiphysis down to the line of the separation. The operator then claps his hands beneath the lower part of the thigh and draws it steadily upwards, gradually flexing completely the knee and hip-joint, whilst the assistant still keeps up the traction on the leg. It will be seen that this maneuver causes the epiphysis to move back upon the fractured surface of the diaphysis until it has reached its normal position and further movement is prevented by the periosteum coming into tight contact with the anterior surface of the femur. A bandage is then applied around the thigh and ankle, fixing the knee at an angle of about 60 degrees. Complete flexion—i.e., heel on buttock—was found in the last case to be unnecessary, and the wider angle is more comfortable. The limb is laid on its outer side on a pillow, and an ice-bag can conveniently rest upon the front of the knee to limit effusion. The advantages of maintaining this position for a fortnight are that the quadriceps exerts tension in the length of the bone, keeping the surfaces in close apposition and squeezing out effused blood, and that the tendon of the quadriceps and the patella fit into the groove between the two condyles and prevent lateral displacement; and since the tendon of this muscle changes its direction at a right angle to be inserted into the tubercle of the tibia, it prevents recurrence of the forward displacement of the epiphysis. The flexed position also removes the sharp end of the diaphysis as far as possible from the popliteal space and relaxes the skin, vessels, and nerves completely. The articular surfaces of the epiphysis are subcutaneous and uncovered, so that their position can at any moment be observed, and the dorsalis pedis and posterior tibial arteries are not concealed by any splint or apparatus. After fourteen days the limb can be extended, under gas if necessary, and put up in plaster in a position about 30 degrees short of the straight line. The patient can then get about on crutches.

In a previous paper the authors recommended that extension should be carried out slowly upon a MacIntyre splint and should occupy a fortnight, but as a rule they have found this caution unnecessary. The plaster remains on for from a fortnight to three weeks, and a little massage restores the movements of the joint.

The authors closed their paper with the following conclusions:

1. That separation of the lower epiphysis of the femur is a very serious injury and is attended when compound by a high mortality.

2. That in the extended position of the knee, even with an anesthetic, reduction of the fragment is very difficult if not impossible.

3. That when the epiphysis is not reduced, the patient is laid up for about three months and is lame for about six months, whilst the end of the diaphysis frequently requires removal by operation. Shortening of the limb and secondary curves in the spine always follow.

4. Nevertheless, the ultimate result in most cases that recover at all is good. The articular surface of the femur gradually grows into a useful position.

5. That with the method of full flexion reduction is always easy, the treatment is short, and it is the rule to obtain perfect movement in the knee without shortening or deformity of the leg.

DEATHS AFTER CELIOTOMY.

Smyly (Medical Press and Circular, April 26, 1899), under this title, classes as the causes of death after celiotomy, shock, hemorrhage, ileus, uremia, inanition, tetanus, embolism, and sepsis.

Under shock the effect of exposure of the
intestines to air is considered, and the need of an absolute hemostasis pointed out. As a preventive treatment the author suggests that, in weak and debilitated patients with weak hearts and rapid pulse, operation should be if possible postponed or abandoned. He advocates the injection of sterilized salt solution, and the means customarily employed in hospital practice. Saline infusion is, however, to be used only when there has been marked loss of blood.

Ileus, if cases of paralysis due to peritonitis are excluded, is generally due to adhesion of intestine to raw surfaces. A stormy onset is exceptional. The obstruction is often incomplete, and the bowels may be evacuated at intervals, and yet the patient may be lost. Washing out of the stomach and deep enema are suggested. When these measures fail the abdomen should be reopened without further loss of time. As to prophylastic measures Trendelenburg's position is one of the most important, since the bowels are out of the way and are not disturbed. Moreover, all raw surfaces should be covered with peritoneum. Coating raw surfaces with collodion has been recommended, and Martin, of Berlin, introduces a sponge soaked in sterilized oil, but most operators attach more importance to drawing down the omentum between the abdominal wound and the intestines, and as far as possible covering all raw surfaces with peritoneum.

Thrombosis is a potential embolism, and as it may be set free even at a late period, the patient should be cautioned against violent efforts or straining for some time after an abdominal operation.

Peritonitis, when this develops, should be treated by free purgation. This inflammation is often aseptic.

FOUR CASES OF INTUSSUSCEPTION.

Morison (Medical Press and Circular, April 26, 1899) reports the case of a child (female) three months old, who for four hours had been suffering from intermittent attacks of crying, accompanied by diarrhea. The stools were mucoid and tinged with blood. The child had been constipated since birth. When first seen it was sleeping restlessly on its mother's knee, but was roused at intervals of ten or fifteen minutes apparently with griping pain in the bowels. Paroxysms were ushered in by a shriek. The legs were drawn up, and the child writhe about in agony. At the same time the bowels acted. The child also vomited frequently. No abdominal tumor could be felt. A large injection was tried, apparently without good result. Operation was refused. The patient was kept mildly under the influence of morphine for a week. On the fifth day a sausage-shaped mass could be felt along the course of the ascending colon. During the second week the symptoms remained the same, excepting that vomiting was less frequent. The child emaciated rapidly and progressively. Sixteen days from the date the child was first seen there was passed per rectum a twelve-inch mass of intestine. A year later the baby was perfectly strong and healthy.

The second case (female) was eleven months old, and when first seen had been vomiting constantly for ten days. The child sustained a fall, and the next day suddenly developed violent vomiting and screeching, passing in a short time per rectum a large quantity of blood. A sausage-shaped swelling was distinctly felt in the area of the descending colon, and per rectum a mass could be palpated, extending down to within an inch of the anus. The child died in a few hours. A post-mortem examination showed the peritoneal cavity to be flooded with intestinal contents. The lesion consisted of an intussusception of the ileum through the ileocecal valve. This had been forced in through the ascending into the transverse and descending portion of the colon, sigmoid flexure, and rectum. At the splenic flexure the intussuscipiens had been perforated and the mucous membrane of the ascending colon projected through the opening. The invaginated small intestine reached to within an inch of the anal orifice.

The third case (male) was three years old. On the morning following a dose of castor oil the child was seized with severe abdominal pain, accompanied by diarrhea and sickness. In twenty-four hours the motions became mucoid and contained a considerable quantity of blood. In the line of the descending colon a sausage-shaped mass could be felt extending from the costal margin to the left iliac fossa. The anus was patulous, but on introducing the finger a body resembling a soft cervix and os uteri could be felt. Large enemata were given, under chloroform, both of water and air; these failed, though they were tried repeatedly. Operation was finally performed three days after the beginning of the symptoms. There were no adhesions, and the invagination was gradually reduced. The splenic flexure had become
invaginated into the descending colon. The patient died within twenty-four hours.

The fourth patient (male), five years old, after some imprudence in diet was taken with very severe pain in the bowels and vomiting. Two and a half hours later he was pale and pinched in appearance, with a rapid, weak pulse. Between the intervals of pain he lay exhausted, and as soon as pain came on he cried out and rolled about the bed. Each paroxysm of pain was followed by an evacuation of mucus and a little blood. The abdomen on examination was quite flaccid, nor was there tenderness except in the region of the right iliac fossa, where a small, elongated, very tender mass could be felt. Insufflation, massage, and large enemata of hot water were tried in vain. Operation was then performed. The intussusception was of the ilio-caecal variety. About a foot of the gut was readily released. The mesentery of the intussusception was then shortened by inserting a few fine silk sutures parallel with the gut, for the purpose of preventing a recurrence. The patient made an uninterrupted recovery.

THE CONDITIONS OF SUCCESSFUL OPERATION IN EPILEPSY.

Kocher (quoted in Medical Press and Circular, April 26, 1899), in a paper on this subject, thought pessimism in regard to operation for epilepsy had been carried too far. From recent experience he had concluded that the method of operation practiced had not been the right one. V. Bergmann had introduced an improvement by removing the cortical portion from which the epilepsy started. About ten per cent were cured in this way. Since the eighties the speaker had operated after a theory of his own, and had obtained six complete cures in traumatic epilepsy. He had collected 175 cases of operation, only calling those cures that remained well at the end of three years, although epilepsy sometimes returned even later than that. In this investigation he was able to determine that that treatment was successful which attacked the cause of the epilepsy direct. After extraction of foreign bodies from the skull, and especially from the brain, eighty-eight per cent of recoveries took place. In the latter cases, where the dura was incised, the results were the best. He assumed that an essential cause of the occurrence of attacks was tension, which was relieved by incision of the dura. Perhaps this reduction of tension was the factor in these cases that had been cured after incision of the cortical center, and also in those cures in which the center could not be determined by electricity.

In the author’s successful cases the covering over the opening had remained soft, so that “giving” could take place on pressure, whilst in the unsuccessful ones the covering had become bony or at least of tense connective tissue. If the principal factor of the attack was assumed to be a cicatrix or adhesions, operations should not be performed, as a cicatrix was always left by them. But these need not be feared. Aseptic soft cicatrices, even when they projected into the brain, almost never caused epilepsy. Guinea-pigs could be made epileptic by a simple blow on the head, and in these cases the blood-pressure was increased fourfold. If the animals were then operated on and a lateral ventricle opened, the epilepsy ceased. An etiological connection between increased pressure and epilepsy had thus been experimentally proved.

In this way cysts and collections of fluid of all kinds within the brain easily gave rise to epilepsy.

According to these views, we have first of all in our operations to remove all local irritation, such as foreign bodies, and then take measures for reducing local and general blood-pressure within the calvarium. The dura when incised should not be sutured, but should rather be excised, and the defect should not be covered by bone. In penetrating wounds of the head the damage was not caused by the opening, but by the firm closure of the skull.

Bergmann said it was yet to be determined what was the nature of epilepsy, and then there was the proposition that there was no epilepsy without spasmodic changes in the brain. This condition was congenital, and it would not be too much to say that in nine-tenths of the cases of epilepsy, whether traumatic or not, there was a hereditary tendency. If we took from the remaining tenth all the cases in which infective diseases were the cause, the remainder would be very small. Hereditary disposition could not be assumed when the attacks began after the twentieth year. As to the cases operated on, it was very difficult to determine whether they had a hereditary predisposition or not. There were two categories of causes of epilepsy: first, the supposed epileptic change in the brain, which could be treated by operation, bromides, and section of the sympathetic; and secondly, where the disease was caused by localized peripheral injury, and here we
must satisfy the indicatio causalis. If excision of the cortex did not always succeed, it was because general epileptic changes had already been set up in the brain. For fulfilment of the indicatio causalis operation should not be too long delayed. A definite judgment as to results of operation could only be given after they had been performed.

ON THE USE OF ANTISTREPTOCOCCIC SERUM IN INFECTIONS BY THE STREPTOCOCCUS.

BRISTOW (Medical News, May 6, 1899), after a brief review of the theory of serum treatment, recalls the fact that in 1895 there appeared an article by Marmorek, in which he announced that he had succeeded in producing a serum effective against the organism of erysipelas. Subsequent articles by the same investigator appeared in other journals, in which he detailed the results of his work in erysipelas, scarlet fever, and other affections in which the streptococcus was the cause either of the disease itself, or, as in scarlet fever, of serious complications. Since then many observers all over the world have reported cases in which Marmorek’s remedy against this, the most dreaded of the pyogenic organisms, has been successfully used. Other observers have reported negative results in similar cases, so that at present there is much confusion in the evidence submitted for adjudication. On the whole, however, it seems favorable and of sufficient weight to justify us in putting it to the test in suitable cases. It thus becomes the duty of those who have made use of this antitoxin to put on record their experience and conclusions with regard to its usefulness. Accordingly he submits the histories of fourteen patients classified as follows: Erysipelas, 3; streptococcic inflammations of the hand and forearm following so-called poisoned wounds, 7; streptococcic inflammation of the leg and foot, 1; suppuration of the knee-joint, 1; postoperative pneumonia, 1; acute gangrene of the foot with an ascending lymphangitis and phlebitis, 1.

The conclusions drawn from these fourteen cases, which are reported in full, are as follows: Cases of cutaneous, or so-called idiopathic, erysipelas may be quickly terminated by the early use of antistreptococcic serum, the initial dose being from ten to twenty cubic centimeters, according to the severity of the case, followed by additional doses if necessary. Rarely more than two or three injections will be required. With regard to the cases of phlegmonous inflammation, the use of the serum has seemed to prevent the extension of the infection beyond the parts first attacked, but has had little if any effect on the sepsis produced by the retained pus. In other words, the same necessity exists, whether the serum be used or not, to secure prompt drainage and the evacuation of the products of inflammation. This agrees with the experience of Marmorek himself, who in reporting ten cases of phlegmonous inflammation states that if the serum is used before the appearance of suppuration this does not occur. If foci exist, when evacuated rapid recovery ensues without extension of the inflammation. Postoperative pneumonia, unless of streptococcic origin, cannot be expected to improve under serum-therapy until we are provided with a mixed serum which shall be protective both against the streptococcus and the pneumococcus.

A complete summary of the literature on the subject shows that the serum has been used in 476 cases of erysipelas, 456 of which were reported by Marmorek himself, leaving 66 reports by other observers. Marmorek states that the average mortality of the disease in the erysipelas wards of the Paris hospitals is five per cent, whereas in a series of 306 cases, excluding three patients who died from causes unconnected with the erysipelas, the mortality when the serum was used fell to 1.44 of one per cent; also that of the 306 cases, 141 were mild and 165 were serious. The serious cases furnished the two deaths, a rate of but 1.27 per cent, in 165 cases of grave erysipelas. All the patients whose cases have been reported by other observers, including the author’s, recovered. Among these was a case occurring in an infant aged three weeks (Charrin and Rogers); another in an infant aged six weeks (Ganchev); one in a baby aged three weeks (Steele); and one in a child aged four weeks (Poliwko). The average dose in the case of infants seems to have been about five cubic centimeters. Marmorek, in reporting a series of ninety-five cases, expressly says that the serum does not at all influence the course of the disease, which depends on the scarlatinal poison, whatever this may be, but only affects those complications due to streptococcic infection, such as the sore throat, the glandular swellings, nephritis, and otitis media. With regard to these complications, themselves often the cause of death, Marmorek makes the following statements: In nineteen cases
of scarlatinal bubo in which the serum was used, not one suppurred; albumin disappeared from the urine after one or two injections, and in four cases of suppuration from otitis media this promptly ceased after the use of the serum. The dose given ranged from ten to thirty cubic centimeters in ordinary cases, in grave cases from forty to ninety cubic centimeters.

Baginsky, in his series of forty-eight cases, makes a similar though more guarded report. Low reports the case of a child, said to be dying from scarlatina with acute hemorrhagic septicemia and otitis media, which improved at once under the administration of the serum, recovery taking place after the use of 263 cubic centimeters. On the other hand, Josias reports a series of ninety-five cases and states that the serum apparently was without effect, the mortality not being appreciably decreased. Other writers have had a somewhat similar experience. In the cases imperfectly reported by Fischer it does not appear that the serum was used for the streptococcus infection, but rather in a general way, and without avail. From the evidence at hand, weighing the reports of the different observers, it seems that benefit may be expected when the serum is used, as Marmorek directs, for the complications due to streptococcus. The scarlatinal fever itself, however, will not be influenced.

The puerperal cases merit more discussion than the limits of this paper will permit. The reports which the writer has collected include 201 cases, with a mortality of thirty-three per cent. This is not encouraging, and the opinions are conflicting. In the larger series of cases, such as that of Bar and Tissier, the mortality is much increased by including cases of patients already in extremis when the remedy was used. The same is true of the Philadelphia cases reported by Baldy, Hirst, Noble, and others, in which the serum was not used until the tenth or twelfth day of the disease. The dosage seems to have been small, considering the formidable nature of the infection and the extent of the tissues involved.

The protective power of this serum is low at present and varies considerably, some specimens being fourteen times the potency of others, according to Marmorek's own statement. It seems idle, therefore, to expect results from so timid a use of a relatively feeble serum. If good is to be expected from the use of the serum in this class of cases, it must be used in far larger doses than hitherto. Quantities of less than sixty cubic centimeters a day will not as a rule avail much, and much greater daily quantities may be necessary. Moreover, it must be used early in the disease, before multiple abscesses have formed in the uterine walls and septic thrombi have collected in the vessels of the pelvic structures.

What is the proper dose of the serum? This is a practical question, and at present it can only be answered by saying that too much rather than too little must be given because the serum has not as yet been standardized. An average dose is ten cubic centimeters. Twenty cubic centimeters will often be required, and daily quantities of sixty to one hundred cubic centimeters may be needed. It is possible that the varying experiences of different observers have been due to the use of serum of different degrees of strength. It is not possible to give a definite dosage until the manufacturers succeed in standardizing their products.

Aside from the occasional appearance of erythema and urticaria, the writer does not believe that any serious risks are to be apprehended. In a series of reports of more than 1000 cases collected by the writer, the only instances in which the serum was charged with ill effects were in four or five puerperal cases.

The serum has been used in cases of so-called malignant endocarditis with success, and in the bronchopneumonia of children (forty-five cases, Marmorek) without a single death. This affection, Marmorek states, is almost always of streptococcic origin. Considering the usual mortality of the disease in children this record is noteworthy.

CLINICAL NOTES UPON THE CONTOUR AND CONSISTENCE OF A THOU.
SAND PROSTATE GLANDS.

FENWICK (British Medical Journal, p. 395, 1899; quoted in Journal of Cutaneous and Genito-Urinary Diseases, May, 1899), in examining the prostate, as a routine position prefers to have the patient bent at a right angle over a table or with his hands resting on a chair, with the bladder empty. Where the patient lies on his back, the prostate will be found higher up in the pelvis, and therefore not so accessible to the examining finger.

In urinary tuberculosis, in a large percentage of the cases, the examination of the epididymis and the prostate lends some aid to the diagnosis of the case. In 157 male
patients a deposit was found in the epididymis in twenty-one per cent of the cases, in twenty-four per cent in the epididymis and prostate, in three per cent in the prostate and seminal vesicle, in the prostate alone three per cent, in the prostate and bladder (the latter by the cystoscope) six per cent; so that in fifty-eight per cent of all the cases a deposit could be detected by the finger on the first visit.

The text-books are indefinite and inaccurate as to the forms which the prostate assumes in tubercle. The "shotty" prostates described by some are found in only three per cent, and are of grave import. Massive indurations of prostate and seminal vesicles described by others are found in five per cent of the cases, and generally denote septic inflammation in addition to tuberculosis. The vesicles may become affected before the prostate in fourteen per cent, but this is not common in the early stages.

In watching a case from year to year it will be found that the deposit passes through a variety of stages, and according to the stage, so is the character and contour of the deposit in the prostate, vesicle, and epididymis.

Tuberculous deposit is met with in the prostate under three clinical conditions: in young males who have noticed merely a lump in one epididymis; in young males who have symptoms similar to those produced by stone in the bladder; or in the adult male who complains of symptoms like those of stone in the kidney. In the first class the patient may present a small, painless lump in one epididymis, and in the prostate on the corresponding side a small, insensitive lump may be found near the sulcus, partly buried in the upper third of the lobe.

In the second class the patient may complain of pain at the end of the penis after urination, with undue frequency and occasional hematuria; the urine is lightish and murky from pus. By the rectum a hard knot may be found, buried in one of the lobes of the prostate, and the cystoscope will show that the bladder base is affected. The corresponding epididymis will also in time become the seat of a similar indolent nodule. Such prostatic deposits may remain indolent, or calcify, or become absorbed.

The indolent epididymal nodule may become inflamed, impetus being derived from a gonorrheal attack or trauma. The knot in the corresponding lobe of the prostate may also present a condition similar to that in the epididymis, and may project sharply into the rectum. Further, the rectal mucous membrane over it may become adherent, and then puckered, and it may soften in one spot. The inflammation may extend to the corresponding vesicle. The author is inclined to believe that inflammatory exudation tends to retard the progress of the tubercular disease.

These indolent deposits rarely suppurate of their own initiative. By the absorption of the deposits the prostatic contour and consistency are greatly altered, the lobes become flattened, the consistence leathery, and the outlines confused. A second important point is, that where tuberculous infiltration of the prostate has once occurred, even though healing takes place, the process extends by definite routes. This route generally begins in one epididymis (twenty-one per cent), then extends to the prostate, corresponding side, into the base, and around the corresponding ureteral orifice in the bladder, and then into the corresponding kidney. The route may short-circuit from epididymis to kidney. The process usually keeps to the side on which it started, though a cross-route may be taken from epididymis and prostate of one side to the opposite kidney. The route may be in the reverse direction, from kidney to bladder, to prostate and epididymis of corresponding side, or by cross-route to opposite side, or by short-circuit from kidney to epididymis.

The author strongly condemns bladder irrigation in tuberculous cases, even where there is pus in the urine, and even though there be temporary relief. The patient, in the end, pays too dearly for the temporary improvement.

---

**GANGRENE FOLLOWING THE LOCAL APPLICATION OF CARBOLIC SOLUTIONS.**

**Leipziger (Virginia Medical Semi-Monthly, April 14, 1899),** after reporting a number of cases of gangrene following the use of carabolic acid, states that the consensus of opinion with reference to the use of carabolic acid solutions seems to be:

1. Long-continued use of even the weakest solutions is dangerous. (In his case the length of time was only 12 hours.)

2. Encircling the part with the dressing is given as a predisposing factor. (In his first case the finger which was not encircled also became gangrenous on the top where the dressing was applied.)

3. Idiosyncrasy is possible and quite probable.
4. The general sale of the drug should certainly be restricted.

He adds the suggestion:
5. That the use of carbolic acid solution as a dressing to injuries of the extremities be discontinued in view of the efficacy and equal cheapness of many less dangerous antiseptics.

---

**SURGICAL TREATMENT FOR CEREBROSPINAL MENINGITIS.**

In an editorial article (Medical Record, May 6, 1899) the following comment was made upon the surgical treatment of cerebrospinal meningitis, suggested no doubt by Rolleston and Allingham’s successful operation.

“What has been done successfully for other intracerebral and intraspinal conditions—such as hemorrhage, effusion, cysts, tumor, etc.—it is now proposed to do in suitable cases of cerebrospinal meningitis, of which Rolleston and Allingham (Lancet, April 1, 1899, p. 889) report a case treated by laminectomy, incision of the dura mater in the dorsal region, and drainage, with recovery. The patient was a man twenty-four years old, who was seized with pains that became diffuse, who experienced a dull, singing sensation in his ears, with deafness, and who presented mental wandering, with an inability to reply pertinently to questions. The knee-jerks were normal; vomiting occurred, and delirium was present at night. The patient lay on his right side, with the thighs and knees flexed. The head was retracted, the muscles of the neck were rigid. There were, further, headache, tache cérébrale, occasional convergent strabismus, variation and inequality of the pupils, and horizontal nystagmus. The patient grew worse, the temperature rose, the skin became red and swollen, and coma and delirium alternated.

“As it appeared that the man would die if left alone, other treatment having failed, surgical intervention was undertaken, an incision six inches long being made over the spines of the lower dorsal vertebrae, of which the laminae of the seventh and eighth were excised. The exposed dura bulged and was incised for about an inch in the long axis of the cord, with the escape of coagulated lymph and cerebrospinal fluid, to the amount of about three ounces. A drainage-tube was inserted, and no attempt was made to unite the incised margin of the dura mater. The skin was loosely approximated by nine sutures, and the usual antiseptic dressings were applied. Decided improvement at once ensued. There was a free discharge of clear fluid from the wound, necessitating a change of dressing twice daily. For three and a half weeks the discharge continued, being impeded from time to time as the wound healed, when the temperature would rise and the symptoms be aggravated. By the thirty-fourth day the temperature remained normal, the discharge diminishing and finally disappearing. The tube was removed on the fortieth day, and the wound was completely healed eleven days later.”

---

**THE RADICAL TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA.**

Rex (Maryland Medical Journal, May 6, 1899) strongly advises in cases of purulent discharge from the ear that has existed for a considerable length of time the institution of a surgical treatment, if a month devoted to simple cleansing and antiseptic applications is not productive of good results.

Two methods of operating are receiving to-day a great deal of attention. The first is ossiculectomy. By removal of the malleus or incus, or what remains of them, we improve the opportunities for drainage, and in a certain number of cases may secure good results. This method is not applicable to all cases, of course, and only cures about fifty per cent of the cases in which it may be resorted to. It does not very much improve the chances of cleansing the antrum, and that is the most important point involved. It fails, then, in that it is not sufficiently radical.

About ten years ago two German surgeons, Professors Stacke and Zaufel, each acting independently of the other, suggested a much more complete and more satisfactory method of treatment, though at the same time a more severe measure. This consists in the removal of all diseased tissues and the converting of the antrum, the tympanum, and external auditory canal into one large cavity, which is to be lined by skin. Both methods accomplish the same ultimate results, and differ only in technique. Preparations for both are made in the same way. The area above and behind the auricle is shaved and thoroughly cleansed, every precaution being taken to make the operation as nearly aseptic as possible. The operation begins in the usual manner by performing a Schwartzte mastoid operation; an incision, beginning at the upper border of the auricle and running down to the tip of the mastoid process, is
made through the skin, the periosteum is elevated so as to lay the whole mastoid process bare, and the auricle is pulled forward by an assistant so that the cartilaginous portion of the posterior part of the wall of the external auditory canal can be separated from the bone through its entire length. In the Schwartz-Stacke method, the removal of the bone begins at the junction of the external auditory canal and the tympanum, and the operator works out toward the antrum; but the majority of operators seem to prefer the Schwartz-Zaufel method, which begins with the usual opening into the antrum, is continued by the removal of all diseased bone in the mastoid process, and is followed by the removal of the bridge of bone between the antrum and middle ear, which forms the posterior wall of the external canal. By each method the ossicles, or such fragments of them as remain, and the tympanic membrane are removed. The next problem consists in securing a skin lining for this large cavity, and various measures have been suggested. Skin flaps may be taken from behind the auricle or from the external auditory canal, or Thiersch grafts may be used. The perforation behind the ear may or may not be closed. These are minor details, however, and can only be decided for the case in hand.

A FEW REMARKS ON THE DIAGNOSIS AND TREATMENT OF RUPTURE OF THE BLADDER.

THORNDIKE (Journal of Cutaneous and Genito-Urinary Diseases, May, 1892) says that so much success has attended the suturing of bladder wounds that many operators do not hesitate to open the bladder into the peritoneal cavity in the endeavor to obtain plenty of room for suprapubic operations; and Dr. F. B. Harrington, of Boston, in an article in the Annals of Surgery for 1893, page 408, "On the Feasibility of Intraperitoneal Cystotomy, with Report of a Case," advocates this procedure in suprapubic operations. His method of operating is to make a long incision into the abdomen, pack off the intestines very carefully with gauze, and then having isolated the bladder, to open it freely so as to get a good view of its interior. He claims great ease of inspection as well as facility in the removal of the offending tumor, stone, or prostate. So that, in spite of the fact that a comparatively few cases of intraperitoneal rupture of the bladder have recurred after suturing of the rent, yet the experience of the last fifteen years (since Mr. Walter Rivington, surgeon to the London Hospital, laid down the rule that intraperitoneal rupture means immediate laparotomy) is such that we have come to consider this procedure as a firmly established principle of surgery. The ease with which accidental and other bladder wounds are repaired has greatly aided the establishment of such a belief.

Immediate operation, then, is the one thing which offers us hope, and is the one thing to be accomplished in as many cases as possible. Any aid to an immediate diagnosis or any formulation of operative indications which will justify immediate operation in doubtful cases is to be desired.

Now, if it invariably happened that the earliest symptoms of bladder rupture were positive enough and clear enough to show that the rent was present, and whether it was intra- or extraperitoneal, it would be clearly our duty to operate in every case. Unfortunately this is not the case, and it is by no means an uncommon occurrence that the delay believed to be necessary to make a more exact diagnosis is the deciding influence between the life and death of the patient. There can be no delay once a rupture of the bladder is diagnosed or even suspected. The time to operate is then and there, and the only excuse for not doing so is that the patient's condition is such that operation will surely prove fatal.

The diagnosis of intraperitoneal rupture is often easy, but can seldom be made positively and immediately without the assistance of the bladder-injection test. We may or may not have in any one case the history of injury, the initial shock, pain, frequent passage of bloody urine in small quantities, urgent and well-nigh constant desire to urinate, the empty bladder with free fluid in the peritoneal cavity, etc., etc. The point is this: there is no time for careful study and extended observation. The decision as to operation is to be made then and there, and the cases are few where such immediate operation can be fully justified without the aid of the information furnished by the injection of a measured amount of fluid into the bladder through a soft-rubber catheter, and the measuring of the amount which flows out again.

Dr. Charles K. Briddon, of New York, in a paper on "Intraperitoneal Rupture of the Bladder," published in the Annals of Surgery
for December, 1895, speaks of this aid to diagnosis as follows: "I regard the institution of this measure as of very doubtful utility and not free from the danger of spreading the infection over a larger area than that already involved by the existing extravasation, and it also incurs the danger of breaking up such adhesions as do occasionally limit the effusion." This criticism is perhaps a just one, but at the same time it implies that the injury is no longer a recent one at the time the test is made. It is the writer's belief that most cases of bladder injury fall into medical hands almost at once, and that, in spite of the fact that in some of the cases the serious character of the injury is masked by alcohol, or by other serious and coincident injuries, there is usually something to lead one to suspect the existence of this accident. Even the slightest suspicion should be followed by the injection test, and the question of operation settled then and there in the great majority of cases. The cases when such immediate decision can be made without the aid of this test cannot be common. The imperative necessity of such immediate decisions does not seem to require further demonstration.

It is not the purpose of the author to enumerate or to discuss individual symptoms, but let us suppose that with or without the aid of the injection test which the writer considers so essential, the diagnosis of rupture is made. More evidence still is needed if it can be obtained—i.e., the knowledge of whether the rupture is extraperitoneal. The injection test may furnish this knowledge by increasing the prevesical tumor and dulness without increasing the amount of or showing the presence of free fluid in the peritoneal cavity, thus establishing the diagnosis of extraperitoneal rupture. The catheter may pass through an empty bladder and then on into another cavity containing bloody urine, thus establishing a diagnosis of extraperitoneal rupture. Occasionally, then, this immediate and accurate diagnosis can be made; more often it can be strongly suspected. Frequently it is impossible to know one way or the other, and only too often must we undertake the treatment of our case with a very imperfect knowledge of the character and location of our injury. How are we to proceed? If the rupture is known to be extraperitoneal we may drain through the perineum. That will serve for a time, perhaps, as a very inefficient drainage which may prevent any further accumulations of extravasated fluid, but will certainly prove inadequate in most cases, for the one object of the operation is the drainage of the urine already extravasated and the drainage of the bladder to prevent further extravasation. Or we may make a prevesical incision over the pubes and drain in that way. If we do we are opening up a dirty cavity full of putrefying urine just previous to opening the peritoneal cavity to search for further trouble there, and we are also contenting ourselves with draining in a very imperfect manner an extravasation of urine, of the extent of which we know little. The cases to which such prevesical drainage is applicable are those extraperitoneal ruptures where the rent is anterior and where the extravasation is also sharply limited to the space of Retzius. Unfortunately we cannot often have such accurate diagnosis at our disposal to aid in the selection of the operative procedure needed. We may make an incision into the bladder (suprapubic) and search with the finger for the seat of the injury, but this must be very uncertain and unsatisfactory in many cases, and even if the tear or tears are found, we still shall not have the information we want as to the extent and direction of the extravasation.

So that, given the doubtful cases of extraperitoneal rupture with extravasation of unknown quantity and direction, none of the above methods is adequate.

Now a word as to these extravasations: they may extend up on the anterior wall of the abdomen, down around the neck of the bladder, or down one or both sides of the pelvis, under the peritoneum. They may go in one or all of these directions, and it is more often than not impossible to tell early in the history of the case without resort to operative exploration. If this exploration is made over the pubes and an extravasation found there, it by no means follows that there is not a deep extravasation as well which suprapubic drainage alone will fail to care for. The author believes that this was the condition in one of his cases, and that a laparotomy would have developed the extent of the extravasation and made the most complete and thorough drainage possible.

Lastly comes the question of where to make the incision, and how to place the tubes for the best drainage of effusions in different parts of the pelvis. If the effusion is in front of the neck of the bladder, and the opening has been made into it by the suprapubic incision without opening the peritoneum,
the bottom of the effusion should be sought with the finger, and a drainage-tube carried down to it.

In opening the bladder for drainage in such a case it may be worth while, if there is evidence that the effusion is making its way backward, to make the lateral perineal cystotomy rather than the median, because in the lateral position the parts about the neck of the bladder are more freely opened, and if the urine finds its way in that direction, it is afforded a sufficient outlet. By the median operation, unless the incision is carried back into the prostate, there is danger that the parts behind the triangular ligament will not be thoroughly laid open, and that any urine which found its way in that direction might not freely escape.

When, as so often happens, the effusion finds its way along the loose tissue on the side of the pelvis, and, as in one case, up along the iliac vessels toward the renal region, perhaps no better incision can be chosen than that which is used for tying the common iliac vessels. In order to give the most direct drainage, and at the same time not to have any more pressure from the tube upon the iliac vessels than can be helped, the incision had better be made rather more toward the median line of the abdomen than is usually done for tying the iliac artery. In this way the tube goes down more directly, and does not make so sharp a bend where it dips into the pelvis over the vessels. If, however, the effusion has already reached up behind the peritoneum, above the brim of the pelvis, the incision must be made further out near the anterior superior spine of the ilium in order to give the best drainage. The finger introduced from this region can penetrate quite readily over the brim of the pelvis, and well down behind the bladder, while the peritoneum separates so easily that a considerable channel can be made, through which the sloughing connective tissue can afterwards discharge itself. Ordinarily, these anterior openings afford tolerably satisfactory drainage for pelvic abscesses, as the intra-abdominal pressure is sufficient to force out the pus even through an unfavorably placed opening.

In any case in which a suppurating cavity has formed in the bottom of the pelvis, which does not drain satisfactorily through an anterior opening, it is perfectly possible to reach it, and give it good drainage, by adopting the incision usually employed for excision of the rectum, and removing the coccyx and one side of the lower segment of the sacrum. Such a wound as this, which bears the name of Kraske, who uses it for the excision of the rectum, gives thorough access to the lower part of the pelvis, and would give excellent dependent drainage in case of an abscess which was burrowing in that region, and which did not sufficiently discharge itself through the more anterior openings.

In conclusion, then, it would seem that there are very few cases of rupture of the bladder, either extra- or intraperitoneal, where a laparotomy is not indicated. It is perhaps proper to formulate these remarks somewhat as follows:

Immediate operation should be performed in all cases where a rupture is known to exist.

In all intraperitoneal cases immediate laparotomy should be performed and the wound in the bladder sewed up.

In all cases where there is any doubt as to whether the rupture is extra- or intraperitoneal, immediate laparotomy should be performed.

In all extraperitoneal cases where there is any doubt as to the direction and extent of the extravasation, laparotomy should be performed at once for exploration and diagnosis, and should be followed by the operation appropriate for the drainage of the case.

There remain only the cases where the rupture is known to be extraperitoneal, and where the extravasation is known to be limited to the prevesical space, as the ones where it is safe to drain above or below, or both, without an investigation of the bladder and its neighborhood through an abdominal incision.

---

THE USE OF EGG MEMBRANE IN OPHTHALMIC SURGERY.

COOPER (Ophthalmic Record, May, 1899), stimulated thereto by reports in which egg membrane was successfully used in brain surgery and to close perforations in the tympanic membrane, employed this material in a case of symblepharon, in one of burn, in one of corneal ulcer, and after iridectomy where infection was feared.

In the case of symblepharon, due to powder burn, the upper eyelid was completely adherent to the eyeball from the caruncle to cornea, extending upward and to the median line. So firmly was the lid attached to the globe that the outward excursion was greatly impaired. After removal of all the cicatricial
tissue, two raw surfaces were left, too large to be covered by conjunctiva.

A large piece of egg membrane was cut to cover the denuded surface on the eyeball, overlapping so the edge could be tucked into a pocket made in the conjunctiva below and above to hold the membrane. This was placed in position, the lids were closed, and a compress bandage was applied. At the end of ten days the membrane was removed; the surface on the ball and lid was smooth, and there were no adhesions. The result was perfect.

In the next case, one of burn, when the granulating stage had been reached the egg membrane was placed between the raw surfaces; it was removed several times, cleansed, and replaced. At the end of ten days the surface was perfectly smooth, and there were no adhesions.

In the other case, one of sloughing ulcer of the cornea, perforation was imminent; this actually occurred while the ulcer was being curetted. Egg membrane sufficiently large to cover the anterior portion of the eye was applied. Atropine was instilled, the lids were closed, and both eyes were firmly bandaged. The third day the eye was opened and examined. The anterior chamber had reformed, the iris was free, the pupil dilated, and the ulcer was healing. The egg membrane was removed, cleansed, and replaced. At the end of the second week the ulcer was sufficiently healed to remove the membrane.

The fourth case was one of iridectomy. A piece of egg membrane was placed over the incision. The wound healed promptly.

The advantages of the egg membrane are that it is easily obtained, easily applied, and produces no pain or irritation; it is aseptic, is not acted on by secretions, and can be removed, cleansed, and replaced; it is firm and elastic, and adapts itself to the parts wherever applied.

Reviews.

We have already reviewed the earlier volumes of this exceptionally valuable work, and turn with much interest to the perusal of Volume VI, which deals with the continuation of the subject of Diseases of the Circulatory System, and then follows with articles upon Diseases of the Muscles, of the Nervous System and its Coverings.

The volume opens with an article upon Right-sided Valvular Diseases by Dr. G. Newton Pitt, and one upon Angina Pectoris by Sir R. Douglas Powell. It is needless for us to state that both of these articles are exceedingly valuable from a clinical point of view, particularly that of Sir Douglas, for the writer's experience in a country where true angina is more prevalent than in the United States has given him exceptional opportunities for its study.

Dr. Roberts follows with a very good article upon Diseases of the Mediastinum and Thymus Gland, and then follow classical articles upon Thrombosis and Embolism by Professor Welch, of Johns Hopkins Hospital, and others upon Arterial Degenerations by Dr. Mott, Aneurism of the Aorta by Professor Sir W. T. Gairdner, and others upon Aneurisms of the Abdominal Arteries and Lymphatic Vessels by Dr. Rolleston.

One of the most interesting articles in the series of Diseases of the Muscles is that by Dr. Hale White upon Thomsen's Disease. Dr. Bevan Lewis writes interestingly of the General Pathology of the Nervous System, and Dr. Head, who is so well known for his researches upon the distribution of the superficial nerves, writes upon Trigeminal Neuralgia.

The article upon Diseases of the Vertebral Column, Tumors, and Compression Palsies is by Professor Horsley.

It is well pointed out in the articles upon Mediastinal Growths that while statistics indicate that carcinoma is the most frequent growth, in all probability sarcoma is the more common in this neighborhood owing to the lack of epithelium and large amount of lymphatic tissue. The incorrectness of statistics probably depends upon the fact that many years ago no clinical distinction was made between carcinoma and sarcoma.

From the first to the last page this volume teems with valuable clinical information, and the series is of distinct credit to English medicine and to its distinguished editor, Professor Allbutt.

Dr. Hirt's excellent book upon Nervous Diseases is well known to readers of medical
German, and since its translation into English by American clinicians has proved itself a popular handbook in this country.

Although the title-page of the present American edition gives no intimation that it is the presentation of a later German edition than the first American edition published some years ago, an examination of its pages shows, nevertheless, that it has been subjected to revision and that the book has been brought up to the more advanced stages of present neurological knowledge. In many ways it has seemed to us that Dr. Hirt's book is one of the best upon this subject which the general practitioner can obtain, for it affords him not only the information which Professor Hirt has obtained by large clinical experience, but also refers so frequently to contemporaneous neurological literature that it thoroughly mirrors present medical knowledge, and while the views in some cases differ from those commonly held by American neurologists, it is certainly an authoritative work.

In the chapter upon epilepsy we learn with interest several facts with which we confess we were not familiar before. He tells us that certain substances taken as food or for their agreeable effects, or as medicines, are very dangerous to epileptics; among these are alcohol, mushrooms, certain spices such as Cayenne pepper and paprika, and also narcotics, particularly cocaine. "Cocaine epilepsy" has been described by Heimann, and under certain circumstances other medicines such as antipyrin may act as poisons and provoke an epileptic attack.

Hirt believes that this reference to "antipyrin epilepsy" (so-called) is a very important one because of the common employment of the drug in this and other diseases.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. Volume II. $1.00 a year.

This, the second, volume of Progressive Medicine, the first volume of which we reviewed two months ago, carries out the idea which gave it origin, namely, to give personal and readable accounts of the progress made in the various departments of medicine. The present volume contains articles upon Surgery of the Abdomen, including Hernia, by Dr. William B. Coley; Gynecology, by Dr. John G. Clark; Diseases of the Blood, Diathetic and Metabolic Disorders, Diseases of the Spleen, Thyroid Gland, and Lymphatic System, by Dr. Alfred Stengel; and Ophthalmology, by Dr. Edward Jackson. The names of these authors are a guarantee of the good quality of their work. The articles of Dr. Coley and Dr. Clark are particularly interesting to surgeons and are exceedingly handsomely illustrated.

The fundamental conception on which this work has been built seems to be a belief that syphilis, as a common cause of pelvic diseases in women, is usually ignored; and that the maternal origin of syphilis in the offspring, in consequence of maternal, acquired, or inherited disease, is not sufficiently recognized. In his preface the author states that the prevalence of pelvic disease, modified syphilis, and relative tertiary conditions amongst parous women in gynecological practice, as well as in other departments of medicine and surgery, leads to the impression that the estimate of immunization, as usually accepted in the mothers of syphilitic offspring, is overstated; and that complete immunity as an argument in favor of the maternal origin of syphilis in the offspring is probably fallacious.

Whether the reader does or does not agree with the views expressed by Shaw-Mackenzie in this work, he must concede that such views are forcibly expressed and amply supported by clinical observation. The book is worthy of careful study, and it is especially valuable in that it tends to counteract a certain mental inertia which leads the profession to accept without thought or questioning the text-book teaching of the day.

The therapy advised does not differ essentially from that in common use.

On Fractures and Dislocations. By Professor Dr. H. Hellerich, of Griefswald. Illustrated with 68 Plates and 126 Figures in the Text, drawn by B. Kelitz. Translated from the Third Edition by J. Hutchinson, Jr., F.R.C.S.

This admirable work, well worthy of translation, cannot be too warmly commended. It is copiously illustrated by ordinary cuts, colored plates, and excellent radiographs. In itself it is almost a practical treatise upon the subject; and yet the script which it con-
tains would, if condensed, occupy probably not more than 200 pages.

The remarks upon the prognosis of fractures are peculiarly apt. The author states that a patient with a fracture may be said to be cured only when he is again able to work. Out of 121 cases of fracture of the shaft of the femur, thirty-four per cent were completely cured in this sense, while sixty-six per cent remained permanently damaged. The average duration of time before a cure was obtained was 13½ months.

Plaster-of-Paris bandages applied around a limb recently fractured are regarded as dangerous. When splints are employed, these may be of bent metal, and the molded plaster-of-Paris ones are strongly recommended.

This work is simply invaluable.

This work, most appropriately dedicated to Lord Lister, LL.D., F.R.S., judging from its first volume, is designed as a text-book which shall thoroughly cover the very large subject of Surgical Therapeutics. There is no attempt made to give a summary of the various methods of treatment, but rather the authors endeavor to state exactly and in detail what they themselves would do under given circumstances. Exceptional diseases are not mentioned, space and time being devoted to the conditions with which the surgeon is most commonly called upon to deal.

The first volume is devoted to the therapeutics of inflammation. There is a chapter upon anesthetics; five upon wounds; one upon cicatrices; one upon syphilis; one upon chancre; one upon tuberculosis; and one upon tumors.

As would naturally be expected, the sections upon inflammation are most thorough. The chapter upon anesthetics, by Silk, is also an admirable one, though the confidence he places in chloroform and the freedom with which he uses it will not be acceptable to the majority of American surgeons. In the section which deals with disinfection of the skin, and particularly that of the hands, it is to be noted that Cheyne and his colleague still trust in the antiseptic powers of carbolic acid. They first scrub with turpentine, then with soap and 1 to 20 carbolic acid solution; or better, a 1 to 20 solution of carbolic acid in water, containing 1 part in 500 of corrosive sublimate. The part is then covered with gauze soaked in 1 to 20 carbolic acid solution.

Carbolic acid is an unreliable disinfectant and is extremely irritating to the skin. Other and more modern methods are preferred by the great majority of surgeons.

It is also to be regretted that a better method of purifying instruments is not given than that afforded by thoroughly washing and cleansing them by means of a nail-brush immersed in a 1 to 20 carbolic acid solution; also the method of sterilizing instruments by immersing them in a 1 to 20 carbolic acid solution for half an hour or longer before beginning the operation may be regarded as thoroughly antiquated. One of the minor disadvantages of this method is that it ruins the instruments.

Douching of the wound with a 1 to 3000 sublimate solution is advised. This is certainly in opposition to the practice of the day.

Finally, Lister's gauze, impregnated with a double cyanide of mercury and zinc, is recommended as the most universally applicable and most satisfactory dressing that has yet been introduced. It has not proven itself so to the majority of surgeons.

A confidence in methods advocated and practiced by Lord Lister, and observed and proven at every step by Cheyne, can scarcely be misplaced; yet though cyanide gauze and carbolic acid solution may be, in the hands of the writers of this book, entirely efficient, their general adoption by the profession would be a retrograde step.

This volume is practical and comprehensive. It should prove of great service to both surgeons and practitioners of medicine. The publishers' work is thoroughly commendable.

Correspondence.

LONDON LETTER.

By Raymond Crawford, M.A., M.D. Oxon, M.R.C.P.

The two medical events of the immediate future are the sixth International Otolological Congress, to be held in London in the second week of August, and the meeting of the British Medical Association at Portsmouth at the end of July. For the former meeting a valuable list of communications from aurists of every nation has been announced, and in addition a general discussion on "Indications
for Opening the Mastoid in Chronic Suppurative Otitis Media” will be opened by Professor Knapp (New York), Dr. Luc (Paris), Prof. William McEwen (Glasgow), and Professor Politzer (Vienna). A special feature of the Congress will be the museum of specimens, illustrating the anatomy and pathology of the ear, nose, and nasopharynx, and of instruments, which has been organized with indefatigable energy by Mr. Arthur Cheadle, of London. At the British medical meeting, out of deference to the naval and military associations of Portsmouth, many of the general discussions will be devoted to subjects dear to naval and military practitioners, such as “The Diagnosis and Treatment of Gunshot Wounds of the Abdomen,” “The Prevention and Treatment of Syphilis in the Navy and Army,” and “The Medical Tests Required at Present for Admission to the Public Service.” On paper the most interesting section would seem to be that devoted to diseases of children under the presidency of Mr. Edmund Owen; this section will discuss the “Treatment of Ununited Fracture in Children,” “The Treatment of Pleuritic Effusions in Childhood,” “The Causation and Treatment of Convulsions in Infancy,” and “The Treatment of Inguinal Hernia in Infancy and Childhood.”

Valsols and vasogens are being much exploited now as a base for ointments in place of paraffin. They are said to be oxygenated hydrocarbons, which have a high faculty of dissolving drugs and promoting their absorption through the skin. In combination with some drugs, such as iodoform and menthol, these bases are able to form emulsions with water. They are well spoken of in dermatological practice, but it is questionable whether they possess these properties in the high degree claimed for them.

Mr. Skinner, pharmacist to the Great Northern Hospital, recommends the following formula for allaying the itching, burning sensation of urticaria:

\[ \text{Liquoris hamamelidis, } 3 \text{ ij; } \\
\text{Salis maris, } 5 \text{ ss; } \\
\text{Aquæ destillat, ad } 0 \text{ j. } \\
\]

To be applied freely.

He also speaks very highly of the following cold cream:

\[ \text{Adipis benzoati, } 3 \text{ iv; } \\
\text{Cereæ albae, } 5 \text{ ss; } \\
\text{Cetacei, } 5 \text{ ji; } \\
\text{Boracis, } 5 \text{ ss; } \\
\text{Glycerini, } 5 \text{ j; } \\
\text{Aquæ cologniæsis, } 3 \text{ iijss. } \\
\]

Jamieson publishes a therapeutic note of interest on the cause of the reappearance of pediculi vestimentorum after apparently thorough treatment of clothes. He has found that the ova remain adherent to the fine down on the surface of the body, and hatch out as soon as opportunity offers. Consequently, besides the usual thorough cleaning of the clothes, attention must be paid to the skin as well. Corrosive sublimate baths and mercurial fumigation have both been recommended. Jamieson suggests a warm carbolic bath after the skin has been thoroughly rubbed over with paraffin; or the wearing day and night next the skin of porous bags containing fragments of sulphur.

Dr. Wild showed the Manchester Therapeutical Society some preparations of artificial calamines, which he proposed to substitute for calamine in the treatment of facial skin affections. He found zinc carbonate a much more satisfactory basis than zinc oxide. Jeweler’s rouge (Fe₆O₁₄), which is the coloring matter of real calamine, gave very good results. Armenian bole gave more yellow-tinted preparations, which were frequently suitable. He believed the artificial calamine was preferable to the natural, as precipitated zinc carbonate is finer and softer than the best elutriated calamine.

Dr. Williamson made an instructive communication to the Manchester Therapeutical Society on the palliative treatment of paralysis agitans. He was of opinion that by appropriate remedies much might be done to relieve the persistent trembling. Sound sleep was a first essential, as beyond doubt sleeplessness served to aggravate all the symptoms. To this end he recommended sulphonal or hot whiskey and water at bedtime. Alcohol and even strong tea or coffee during the day appeared to increase the trembling. Writing or needlework, or even holding the arms above the head, was of some temporary benefit; so also the warm bath. Systematic open-air treatment by whatever means most convenient to the particular sufferer should be rigidly insisted upon. Dr. Williamson had tried strychnine, arsenic, potassium iodide, potassium bromide, calabar bean, gelsemium, and cannabín tannate with no benefit. Morphine hypodermically is beyond doubt of great value, but should of course be avoided in a disease of such chronicity; but morphine or duoboline by the mouth seemed comparatively ineffectual. Hyoscine, however, appeared to be the drug of greatest value. Dr. Williamson gave as much as \( \frac{1}{30} \) of a grain of hyoscine hydrobromate at a dose; he had
started with $\frac{1}{8}$- to $\frac{1}{4}$ grain in pill form, but had found such small doses useless. He now gave the larger dose in solution—two teaspoonfuls of a mixture of one-fourth grain of hyoscine hydrobromate in six ounces of chloroform-water. The dose could be increased to $\frac{1}{2}$ grain without fear. Dr. Leech was of opinion that so large a dose as $\frac{1}{8}$ of a grain might be given by the mouth, but hypodermically would almost certainly be attended by alarming symptoms. Hyoscine seemed to relieve the muscular restlessness and tremor. Tolerance for the drug is usually established in the course of a few weeks, when it is better temporarily to abate the remedy, and resume it at a later period.

To the sufferers from hay-fever at this time of the year it will be welcome news that Dr. Burton claims to abort coryza by the local use of a solution of tincture of belladonna in water—a drachm or a drachm and a half in an ounce of water. He gives the following directions for use: The nose having been well cleared out and a Wallar’s irrigator containing about a dessertspoonful of the solution applied to one nostril, close the other nostril and the mouth, and while gradually raising the distal end of the irrigator, make a long inspiration until the air, in bubbling through the solution, carries with it a coarsish spray. Afterwards spray the other nostril in the same way, and then, having well cleared out both nostrils, repeat the process. He vouches for the cessation of the coryza, if the treatment is commenced on the first or second day of the attack, but in cases of longer standing the application may require repetition once or twice in addition. In cases of long standing in which the nasal mucosa is thickly coated with a tenacious mucus, this should be previously removed by warm alkaline irrigations, so that the belladonna solution may act directly on the mucous membrane.

Sir Willoughby Wade makes some practical suggestions on the treatment of abdominal palpitations. This symptom is commonly associated with functional disorder of some viscus or other, and is commonly regarded as an effect of it; hence treatment is directed to the supposed causa causans with the usual unsuccessful results. Sir Willoughby Wade opines that we have to deal with a condition of high tension in a limited arterial area, to wit, in the abdominal aorta and the adjacent iliac arteries. He supports his contention by the observation that in these cases there is usually a low tension radial pulse, the blood being concentrated on a splanchnic arterial area to the privation of a somatic. With a view to restoring circulatory equilibrium, he recommends in these cases a small—say $\frac{1}{8}$ grain—dose of nitroglycerin, when an attack of palpitation sets in. He himself has employed the remedy with constant success, and has noticed also that with relief of the abdominal palpitation the radial pulse becomes more full and forcible. He considers that this is the essential principle involved in the Schott treatment, that relief of one circulatory area is best promoted by determination of the blood to another; the baths attract the blood to the skin, and the resisted movements to the muscles, and by emptying the splanchnic vessels the stasis in them is relieved.

At the last meeting of the British Balneological and Climatological Society, Dr. Shirley Jones spoke enthusiastically of the good results obtained in cases of neuritis and neuralgia by treatment with Drottich brine baths. The general line of treatment for acute cases consists in the use of a hot reclining bath without massage or electricity, but with as complete rest as possible; in cases of the lower limb rest in the recumbent position; for the upper limb rest in a sling; and in uncomplicated cases no drugs at all. Compresses of hot brine water are used for relief of pain. As the acute stage passes off the douche along the course of the nerve is employed. The temperature of the douche varies usually between $80^\circ$ and $115^\circ$ F., according to the patient, but in some cases as low a temperature as $65^\circ$ has been found beneficial. These low temperatures are most suited to cases in which there is muscular atrophy; for these cases the swimming bath is particularly useful, not only on account of its general tonic effect, but also because on account of its buoyancy a limb may be freely exercised with a minimum of exertion.

The vacant chair of Physiology at Edinburgh has now been filled by the appointment of Professor Schafer. No one can doubt that the Curators have selected the right man from among a very strong field of competitors. For research Professor Schafer has of course a world-wide reputation; his experience of teaching ranges over some sixteen years that he has held the post of Jodrell Professor of Physiology in University College, London. At the present moment there are vacant several important professorships and lectureships in physiology in this country; and, moreover, Schafer’s departure to Edinburgh will almost
Certainly involve a shuffling of the cards within the metropolitan area.

The committee of the Liverpool School of Tropical Diseases has decided to send an expedition to West Africa to investigate the causes of malaria with a view to extirpating the disease. Major Ross is to be at the head of the expedition, which will reach Sierra Leone in August. He hopes to establish his theory that malaria is caused by the bite of a certain species of mosquito, and to devise some method of exterminating the mosquito.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

It may interest the readers of the Therapeutic Gazette to read a few lines concerning the Boucicaut Hospital, the newest one in Paris, and which represents the latest applications of architecture to the care of the sick. This hospital is due to the generosity of Madame Boucicaut, the wife of the founder of the Bon Marché, and was opened on December 1, 1897, by President Faure. Ten years before this date Monsieur Boucicaut died, leaving by will two millions of francs to the Administration of the Assistance Publique. If after settling all minor endowments the sum of eighteen millions of francs was left over and above, this sum was to be used to found a hospital in Paris. Certain conditions were specified, of which I shall say a few words as I proceed. A certain number of beds were to be reserved for the employees of the Bon Marché; there should no longer exist that rigorous distinction of the hospital into two parts, one for men and another for women; and instead of having an equal number of beds for both sexes, that for men should be in excess, as is justified by statistics.

The plans offered in a competition differed greatly from what is found in America. Fifteen jurors to decide on the plans were chosen—five from the Municipal Council of Paris, two from the Supervising Committee of the Public Assistance, a physician and a surgeon of the hospitals, one of the executors of the will, three architects chosen by the competitors, the administrative director of the Paris works, and the general director of the Public Assistance. One point will strike my readers: it is the small number of medical men indicated, a fact which is due, first, to their rarely remaining any great length of time in one hospital, and secondly to their rôle in a hospital being a purely medical one, no administrative authority being given them. In former times such a condition of affairs did not exist—for instance, Dupuytren was at one time director of the Hôtel Dieu.

The work on the Boucicaut Hospital was begun in October, 1894, and finished in November, 1897. This building, or rather group of buildings, is situated in the Javel quarter, on the south side of the Seine, in a very salubrious part of the city. By personal observation I have been able to note the freshness and purity of the air compared to that found in the center of the city. The fortifications are only 800 yards distant, and this part of the city is but sparsely populated compared with the rest. Though the hospital contains only 180 beds approximately, it covers an area of 30,000 square meters, of which 7500 only are used for the buildings. The various wards are disposed in parallel lines, north and south, so that they receive the sun on one side in the morning and on the other in the afternoon. Brick, stone, and iron are the materials used, and the roof is tiled. An interesting point is the construction of the walls of the pavilion; they are double, and squares of cork are used in their construction, which serve to prevent any untoward effect from rapid variations in the external temperature.

On entering the building from the Rue de la Convention, a wide street paved with wood, one comes into a large hall, from which branch off right and left the services of medicine and surgery. If we go to the right we pass through a long tiled passageway leading to the consultation rooms, and ending at a small pavilion with four beds, intended for doubtful cases. The patient on entering is shown into a large waiting-room, and if he is admitted he is given a bath, a new suit of clothes, his old being sent down by special openings into the underground passages, whence they are taken to the disinfecting department. If the case is doubtful, it is kept in the isolated pavilion; if not, it is taken either to the general medical ward A or to the consumptive ward B. The same course is followed out in the surgical division, there being two distinct wards—one for septic cases and the other for aseptic cases.

Leaving behind us the long building fronting on the street, and entering the large central court, we find that the space before us resembles a huge garden, with four long nar-
row buildings running parallel to one another and of exactly the same form. I have already mentioned the complete separation that exists between these four buildings—ward B being given over to consumptives, wards C and D having each their own operating-rooms, with the various instruments and articles attached thereto. On entering these wards, one is impressed by the beautiful cleanliness, due, first, to the lack of corners (everything is rounded off, and the roof is ogival), to the great quantity of windows (which are arranged in three sets, with various means of opening them, according to their height from the ground), and to the beautiful color used for painting the walls—a sort of rose hue. The floor is made of large white tiles, and here and there a line of darker hue. The ceiling is at a height of six meters, and each patient's supply of air is about eighty to ninety meters.

The ventilation is assured by orifices existing below the windows, and by apertures in the ceiling opening into small aerating towers. All these wards occupy only one story.

The heating apparatus is placed in front of each window, and heat is supplied by steam. The air, on coming through the ventilators, is therefore heated immediately.

At night one or two blue electric lamps furnish the light necessary for watching the patients.

The steam-heating apparatus and the electric plant are placed in the same building and furnished with steam by the same generator, which moreover furnishes the heat to the kitchen, a fine large room, with a magnificent ventilator, and where one is impressed by the use of enormous boilers for cooking. These are hollow, and it is by having the steam come up into them that a sufficient degree of heat is produced.

At the end of each ward there is a sort of veranda with glass sides of various colors, containing shrubs, where the convalescent patients are allowed to remain during the day.

The beds are made on the Herbet system, and can be taken to pieces completely; the chairs are iron, with wooden slabs; the tables are also of iron, with two porcelain slabs. The furniture of the wards is built in accordance with modern ideas, and is made mostly of iron and glass.

The spittoons are also very well arranged, being placed about a yard above the level of the soil, and containing a solution of carbolic acid. Every morning they are carried off on special carriages arranged for this service and completely sterilized.

The cleaning of the wards is done with water and soap. In every ward there is a small opening that leads off from the floor into a pipe, and in this manner the result of the cleaning can be easily removed.

Dr. Letulle, who has charge of the medical service, has tried to transform the tuberculous ward into a species of sanitarium. He has had a tent constructed where the tuberculous patients can lie out during the hot summer months, and a certain number of wicker chairs with covered tops (bath chairs) are used in the same way.

The surgical service, which is under control of Dr. Gérard Marchand, is very well organized, but there are some minor points which have been neglected, such as a special room for narcosis. The operating amphitheater is too small for the number of assistants, who are obliged to crowd around the operator. The service which is perhaps the best, though presenting some minor defects, is the maternity. This part of the establishment, which is under the direction of Dr. Doléris, is quite separate from the rest of the buildings. (Dr. Doléris, the head of the maternity division, visited the United States some years ago. For a number of years, first in a private clinic of his own, and afterwards in a service at the Pitié Hospital he gave lessons in gynecology with practical exercises. These were much frequented by foreigners, to whom Dr. Doléris was invariably courteous. Dr. Doléris's works are too well known by all gynecologists to need mentioning.) There are two buildings in this part of the hospital—a smaller one adjoined to the street, destined for the infected cases, with a kitchen, two rooms for nurses, and one for a midwife; on the first floor are two rooms with two beds, a small operating-room, a bath-room, and water-closet.

The Maternity itself is a two-story building. On the first floor one finds a waiting-room, a consulting-room with bath-room attached, the reception-room of the physician, a laboratory, and a museum for pathological specimens. In another wing are two rooms for the midwives, a dining-room, a bath-room, a linen closet, a dining-room for the patients, and a ward containing six beds for patients presenting something abnormal. On the first floor there is the "salle de travail," or parturition ward, with four beds; this is one of the finest wards in the establishment. Adjoining is a bath-room, and close by a
large operating room for major operations. The beds in the “salle de travail” are so arranged that the end of the bed can be thrown back and the patient brought to the foot of the bed for a case of forceps or version. The maternity ward is large and spacious and contains fourteen beds. Next to it are two rooms for the wet-nurses, who can watch through the windows all that takes place in the ward. There is adjoining these rooms a room in which it is proposed to wash and weigh the infants every afternoon.

I have so far not spoken of the system of underground passages, which is one of the most striking features of the establishment. Underneath the pavilions there is a long tunnel in the form of a horseshoe, lighted from above by small funnels, and giving off lateral tunnels for the different wards. The whole hospital is therefore connected by this underground system of passages, which exists also in Berlin at the Urbain Hospital. This tunnel serves for the carrying of food on small tramways, and the placing of the water-pipes, gas, and electricity. All the soiled linen is carried off in like manner.

Such is a short description of this new hospital, which presents of course a certain number of defects, but which is after all much in advance of the other Paris hospitals.

QUININE IN MALARIAL HEMATURIA.

To the Editor of The Therapeutic Gazette.

SIR: I have been much interested during the past year in a discussion going on among members of the medical profession of the South on the administration of quinine in malaria in its various forms and complications. Physicians of equal eminence are widely at variance. I am constrained to believe that each line of treatment possesses its quota of merit. My experience has long taught me that in the more malignant forms we at times have to call to our assistance all the resources of the art.

The name “malarial hematuria” I conceive to be a misnomer, calculated to mislead the young and inexperienced physician in its treatment. In speculating on its etiology and pathology (I use “speculating” advisedly), I grope along the well worn paths of experience with no data of a scientific nature to guide or direct me. I concede malaria to be the primary cause, but after the initiatory chill, the characteristic urinary discharges, the intensely icteric condition following, we then have before us manifested in all its intensity the phenomena of biliary poisoning. Cholesterine being the poisonous principle of the bile (Flint’s Physiology), we have cholesteric hematuria, or hemoglobinuria, and as quinine produces cholesterine in the blood (Headland on Actions of Medicines) its administration is clearly contraindicated. The disease in my experience is seldom if ever characterized by periodicity; rigors of varying intensity follow each other in rapid succession, due to the toxins circulating in the blood, also to the altered chemical relationship existing between the blood, the nervous system, and other organs and tissues of the body; the functions of the liver being entirely suspended, a suppression of its action as a destroyer of animal toxins intensifies the peril of the patient. The gall bladder is destined to its utmost capacity by concentrated bile; the ductus communis is occluded by thick inspissated mucus.

The issue of the case depends absolutely upon our ability to keep the kidneys acting until we can arouse the portal system. I will not try in this communication to go into the details of its treatment. Quinine is not admissible at any stage of the disease, nor is it indicated, as it is productive of the disease, its administration often converting a mild case into one of malignancy and hopelessness.

Dermott, Ark.

SNAKE-BITE AS A CURE FOR PULMONARY PHthisIS.

To the Editor of The Therapeutic Gazette.

SIR: It may be of interest to you and some of your readers to hear of a case that fell to my lot to see and treat, especially the result obtained. The case was a woman thirty-five years old, who for three years has had all the typical symptoms of pulmonary tuberculosis; these I need not mention, but suffice it to say they were all present. The patient was bitten in the face, on the malar bone, by a copperhead snake. I used cardiac stimulants and permanganate of potassium by injection (subcutaneously). The patient then weighed 92 pounds and was emaciated and weak. From the date of bite her weight increased to 138 pounds, the hemorrhages ceased, and to make a long story short she is now almost well, the phonendoscope showing only a little trouble.

The Treatment of Apoplexy.

By L. Harrison Mettler, A.M., M.D.,
Professor of Physiology of the Nervous System, College of Physicians and Surgeons, Medical Department of University of Illinois, Chicago.

No disease taxes the skill of the physician more than apoplexy. The diagnosis of the form of lesion causing the symptoms and the determination of the limitations of human interference demand experience and judgment. The fact that so little can be done in a case of cerebral hemorrhage adds to the difficulty of deciding precisely what that little shall be.

The dissimilar methods of management demanded in cerebral hemorrhage and embolic obstruction enhance a hundredfold the need of care in diagnosing the lesion. A misjudgment in the arranging of the position of the patient may mean death instead of life. The administration of a heart stimulant in place of a heart sedative may bring the case to a promptly fatal termination. An unwise attempt to evacuate a full stomach may provoke a renewal of the hemorrhage. A venesection may hasten or retard the end. All these questions must be rapidly and seriously considered in the presence of the patient, who will usually be found surrounded by frightened and clamorous
friends. Few occasions will the physician have wherein he will have more need of his steadiest nerve, readiest wit, and keenest judgment. For that reason it is not inap-
propriate to carefully review the care and management of so frequent and protean a trouble as apoplexy.

In considering the treatment of apoplexy most writers begin by dividing the subject into the prophylactic treatment and the treatment of the attack and sequelæ. It would be better, it seems to me, if the emphasis were laid more upon the treatment of the different conditions of cerebral hemorrhage and cerebral embolism. In confusing these, more serious errors are made than in any other way; and therefore it is of the utmost importance that a clear diagnosis be made and the prophylaxis and attack be handled accordingly. So important is this fact that the consideration of the treatment of apoplexy cannot proceed without a simultaneous consideration of the differential diagnosis. In the prophylaxis this differentiation between hemorrhage and embolism is almost impossible. The history of the case is about all that we have to rely upon. A previous attack of rheumatism followed by endocar-
ditis would predispose to embolic obstruction; likewise would certain deteriorated blood states and circulatory weaknesses suggest embolism. On the other hand, high living, full habit, atheromatous arteries, would incline one to fear hemorrhage. Age counts for something, as well as heredity. But after all it is difficult, and fortunately not so necessary, to differentiate in managing the prophylaxis; for in both threatened hemorrhage and embolism the management of the prophylaxis is more alike than is the treatment of the attack. A quiet life, both physically and mentally, is a desideratum. The digestive and nutritive organs should be relieved of strain and encouraged to functionate normally. The emunctories should all be kept active to rid the system of deleterious sub-
stances. Sleep should be secured. Mental and physical activity should be evenly balanced. In a word, the threatened victim should be induced to lead a life of mild and even tenor, devoid of anxiety and brightened by as much happiness as possible. Beyond this little can be offered in the way of advice against an attack of hemorrhage or embolism.

It is quite otherwise in regard to the attack itself. Now the advice becomes of definite and distinct importance. The differential diagnosis must be made as sharply as pos-
sible. The suggestions to the nurse and attendants must be precise and not open to the least misconstruction. The patient when first seen will be almost invariably found lying flat on his back. Position is an important factor, and it behooves one to decide quickly how to place the patient to the best advantage. Gravity plays a rôle, though a slight one, in the force of the circulation; hence it must be remembered in connection with the nature of the lesion. If the case is one of hemorrhage, a half-reclining position on one or the other side of the body is the best. Heidenhain* recommends that the patient be put in a sitting-erect position and maintained in such an attitude as long as possible. I have seen amelioration of the symptoms by this simple maneuver. Often the friends standing about will strenuously object, but a compromise may be made by propping the patient against the overturned back of a chair in a half-reclining position. While he is in this attitude cold in the form of cracked ice should be applied to the head to cause as far as possible contraction of the cerebral vessels, and heat to the lower extremities to dilate the blood-vessels there and so lessen the blood-pressure in the brain. The latter may be further accomplished by the cautious administration of a cardiac sedative, such as tincture of aconite or vera-

If the case is one of embolic obstruction the reverse of all this should be done. Now we desire to increase the intracranial blood-pressure; for the embolism being already there and beyond the hope of immediate removal, it is our object to check its progress and further development by suddenly making it stationary. To do this the patient's head should be placed as low as possible. The cold and heat may be applied as before, but instead of a cardiac sedative a stimulant now acts more favorably, such as alcohol, am-
monia, or even small doses of digitalis and ether.

The importance of attending at once to the decubitus of the patient is brought out by the fact that undoubtedly some fatalities occur from suffocation. Kind friends, not knowing what to do, put the patient on his back, with head low, and administer brandy, milk, or whiskey. Very often the tongue is partially paralyzed, as well as the pharynx, while the sensitiveness of the buccal mucous

* Berliner Klinische Wochenschrift, Berlin, Feb. 10 1890.
membrane is lost. Saliva and fluids collect, obstruct, and even enter the air-passages, setting up inhalation-pneumonia. The obvious thing to do is of course to raise the head, place the patient on the side, carefully pull forward the tongue, and swab out the mouth with a dry rag or bit of linen moistened with some aromatic, antiseptic mouth-wash.

As the respiratory power is usually diminished, it is important that the patient should have all the fresh air possible. Crowding about his bed should be forbidden, and the windows even in cold weather be more or less open. It may even be necessary to perform artificial respiration, this being done with as little disturbance of the patient as possible, and only until the respiratory centers have sufficiently recovered from their shock to resume their normal functions. All constriction about the neck by tight clothing must be removed, so that the return circulation may not be obstructed. To increase the blood-pressure within the cranium in embolism, it may be well at times to apply the Esmarch elastic bandage to the lower extremities. It would be unwise to do this as a routine measure, but its worth in some cases cannot be doubted. To determine the blood away from the head we have two rapid and powerful methods, namely, bleeding and hydragogue purgation. The old-time practice of placing two or three drops of croton oil on the back of the patient's tongue is a good one. A brisk enema may be employed in some cases, but usually it is too slow in action. The same may be said of elaterium. Cerebral congestion is certainly modified by quick action upon the circulatory and glandular apparatus of the bowel, as can be clearly demonstrated; hence it is a rational conclusion to hold that the same means will be effective in lessening the intracranial blood-pressure in hemorrhage.

In regard to venesection, or the abstraction of ten or a dozen ounces of blood, there is a wide divergence of opinion. At one time it was a routine practice and consequently abused. On the other hand, there are those who boast that they never bleed a patient. Of the two extremes the latter is the preferable one. The abstraction of a few ounces of blood is almost immediately followed by a partial return to consciousness, and hence the one-time popularity of the treatment. It should be remembered, however, that the heart action in anoxemia is usually weakened. Therefore, to still more weaken it by depriving it of its natural stimulus, the blood, is hardly a commendable procedure. Only in sthenic cases with flushed countenance, full pulsating vessels, and a vigorous general physique is venesection to be thought of. The thinning of the blood diminishes its tendency to coagulation at the seat of hemorrhage and lessens its stimulating power upon the medullary cardiac center and heart muscle. In most cases these disadvantages would so far outweigh the possible little benefit due to the mechanical diminution of the intracranial blood-pressure that I am generally opposed to the operation. In the few cases in which I have abstracted blood, it seemed to me that the slight benefit and partial restoration to consciousness were so temporary as to be without any special value. In one case I fear it hastened the end, though both the consultant and myself anticipated the best of results.

All such slow means of withdrawing blood from the head as leeches to the temples, mustard to the nape of the neck, blisters, etc., may be tried in some cases, perhaps most cases; for, fortunately, even if they are slow they are not open to such objections as is venesection. If they irritate the patient they had better be desisted from, for the patient's distress will tend to a return or extension of the hemorrhage.

Diuretics are judicious, and in this connection it is well to mention that catheterization will sooner or later be required in almost every case. The bladder is usually paralyzed to a certain extent and fails to void its contents. Unless the catheter is promptly and systematically used the patient will experience distress, if he does not acquire a cystitis.

The skin should be attended to, and a gentle rubbing of the surface of the body with alcohol and tepid water cannot fail to be of some benefit. The enormous capillary circulation in the deeper layers of the skin may be made to retain a large amount of blood by the application of warmth to the body surface. Moreover, the cleansing of the skin with warm water awakens the activity of the glandular apparatus, and this will aid in determining the flow of blood away from the head.

It will thus be seen that very active treatment immediately after an apoplectic shock is uncalled for. Beyond careful nursing, quietude, arranging of the patient's position, attending to the respiration, nutrition, and
excretions, the physician can give but little advice. If the shock is so severe that death is inevitable, little that art or science can do will be of any value one way or the other. The end will come in a few days or hours, and though the occasional twitching of the muscles of the extremities as a result of the local irritation of the clot may awaken false hopes of a return to consciousness, the physician will serve his interests best by carefully guarding the family against any fallacious anticipations. If, however, consciousness partially or completely returns, and the patient is a hemiplegic with or without aphasia, the physician can do a great deal, not only for the victim’s comfort, but even to ameliorate to a large extent the distress caused by the various sequelæ. In fact, this is the stage of apoplexy in which medical science can play its best hand. The storm has passed; it now remains to restore order as far as possible out of the wreck, and in doing this the attendant can sometimes do wonders. In the first place, every precaution spoken of under the head of prophylaxis should be adopted to prevent a return of the shock. Absolute quiet, mental and physical, with the head elevated; light, nutritious, non-nitrogenous diet; gentle sponging of the surface of the body; abundance of fresh air; and all those agencies calculated to cheer, invigorate, and nourish the patient, so far as he is capable of being so acted upon, should be carefully thought of.

While the clot is undergoing organization and surrounding itself with a capsule, the paralyzed muscles will become somewhat atrophied. To preserve the muscles in the hope of their resuming their function if the nervous centers should regain part of their power, faradism, massage, and gentle passive movements are to be instituted. Just how soon this is to be done is the source of a difference of opinion. In my own experience I have found it advantageous to begin very early—gently, of course, at first—not later than the first or second week after the shock and subsidence of all signs of irritation or possible inflammation. Passive movements and the passage through the muscles of a current of faradic electricity, just sufficiently strong to produce easy, regular contractions, should be made systematically for a few minutes each day. I am fond of using olive or cocoanut oil when giving the massage, as it softens the skin and, I believe, favors to a slight extent the nutrition of the underlying tissues. At no time should anything cold be placed against the body, and at all times the patient should be clad with warm, non-irritating garments. Later on it is a good thing to encourage the patient to attempt voluntary movement. Of course, this will be impossible in many instances, but he should move the well side, and the attendant may assist him by raising at the same time the paralyzed limb. Ofttimes the patient thinks he is doing this of his own will, and the helpfulness which it inspires cannot but be of benefit; nay, more, such simple maneuvers have kept the cortical memory or representative centers alive, so that when the motor areas had partially recovered their function the patient was better able to attempt and even succeed in performing voluntary movement than he otherwise would have been. Reeducation of paralyzed, or rather partially paralyzed, muscles is an important part of the physician’s duty. Many a hemiplegic would have been less hemiplegic if the memories of muscular movement had been preserved by the early practice of passive movement in conjunction with attempted voluntary movement.

What I have just said applies likewise to the aphasia following the shock. The speech center should be encouraged to functionate, or at least an attempt made early in the trouble to awaken the activity of the corresponding speech center of the opposite side. These centers are the memory or representative centers for speech, and hence if a patient is utterly neglected it will happen that when the center recovers from the shock, the power of speech will be much less than it otherwise would have been. Hence, as soon as consciousness is sufficiently restored, I have the nurse for a few moments each day teach as she would a child the names of persons and things, and if possible get the patient to repeat them after her. It is astonishing, in a certain percentage of cases how strikingly and rapidly the aphasic symptom may in part be recovered from by this prompt and regular reeducation of the memory centers for speech. In cerebral as well as muscular physiology it is an axiom that exercise increases nutrition and function. Many an aphasic hemiplegic would undoubtedly have been less of an aphasic and less of a hemiplegic by the systematic exercise of his cerebral structures as soon after the shock as possible, and when all signs of inflammation and irritation had subsided.

In all traumatic cases, and in all cases in
which the symptoms indicate a superficial location of the clot, trephining for the removal of the latter is to be taken into serious consideration. I recall the case of a boy of some five years of age who fell over a banister and sustained a severe concussion of the head, with the formation of an intracranial clot with all its accompanying signs of unconsciousness, localization, and stertor. The spreading of the clot immediately after the fall could be clearly observed by the spreading and deepening of the muscular paralysis. Trephining was immediately performed, with a partial restoration to consciousness and a slight return of the muscular power. The action of the muscles was a striking phenomenon. At first they were violently contracted, probably because of the irritative action of the clot; then they became paralyzed completely, with a more or less fixed rigidity. After trephining they relaxed completely, and remained so, or were very feebly moved as a result of subconscious volition. Death occurred in a few hours, however, from exhaustion and shock. The removal of a clot deep in the centrum ovale is a hazardous and difficult operation. It is attempted, however, but with little genuine success. The paralysis in such a case is not relieved, but a source of infection and irritation is removed and makes the operation at least one to be thoughtfully considered.

I have very little faith in the so-called sorbefacient powers of such remedies as the iodide of potash, gold, arsenic, etc. As alternatives they may indeed somehow modify the clot or the results of its presence in the cerebral tissues, but I am inclined to think that much of their effect is due to some kind of stimulant tonic power. At all events, their administration does seem to be of some benefit in some cases, and they are therefore to be recommended.

100 State Street.

DISPLACEMENTS AND DILATATIONS OF THE ABDOMINAL ORGANS; THEIR RELATION TO FAULTY MODES OF DRESS, AND THEIR TREATMENT.

By Boardman Reed, M.D., Philadelphia.

It would be impracticable within any reasonable limits to discuss this topic exhaustively and with full reference to its extensive bibliography. To do so would involve a consideration of the whole subject of the atony of the muscular abdominal walls and of the ligamentous supports of the intra-abdominal organs, with its most frequent primary or direct cause in the unhygienic dress of the great majority of women, as well as the sedentary habits and neglect of exercise in both sexes. We would need to consider, further, the indirect cause of this atony in the lowering of nutrition which results from a deficiency of pure air and sunlight, to say nothing of impropriety in diet, irregular hours of eating and sleeping, the abuse of narcotic drugs, and many other hygienic errors.

Attention will be called, therefore, to the following salient points only of a theme which is of deeper and more far-reaching importance than many physicians even realize:

1. Loose and movable kidneys, which term may be made to include the aggravated stage known as floating kidneys, rarely constitute a single or independent pathologic condition, but nearly always form part of a general disturbance of the abdominal contents, involving also either a dilatation or displacement of the stomach and transverse colon, as well as, in most cases, a marked sagging downward of the small intestines. Exceptionally the liver and spleen also sink below their proper positions.

2. This abnormality of the stomach, intestines, and other organs, notwithstanding assertions to the contrary, is in no sense a consequence of the looseness of one or both kidneys, but all result from a common cause, and even after the kidneys have been fastened in their normal position by an operation the former does not as a rule disappear or get well without appropriate medical and mechanical treatment.

3. This group of displacements, etc., under discussion was first fully described by Glennard in 1887, though in part recognized by others at an earlier date. It was called by him enteroptosis, but a more appropriate name is splanchnoptosis. It is also known as Glennard's disease. Chief among its many injurious results are constipation, nervous dyspepsia (in the earlier stages), and catarrh in various parts of the gastrointestinal tract, including especially the stomach, both large and small intestines, and the appendix vermiformis; also neurasthenia, anemia, insomnia, weak heart, and other symptoms dependent upon the autointoxication secondarily induced.

4. A very large proportion of uterine flexions and versions in the non-child-bearing
woman certainly, and probably also in parous women, are for the most part a direct mechanical result of the pressure from above of displaced colons heavy with retained feces, and low-lying dilated or displaced stomachs, which after a full meal may often be found resting immediately upon the bladder and uterus.

5. Displacements of the abdominal viscera are very much more frequent in women than in men.

In a large number of examinations of abdomens of which full records have been preserved, made during a period covering less than three years, and including the cases of 710 different persons, there were 362 patients in whom the greater curvature of the stomach was found at or below the level of the umbilicus as a result of either displacement or dilatation. There were many other cases in which the departures from the normal were present to a less extent. In exceedingly few—in not more than one per cent—of these 362 displacements and dilatations had the condition been previously recognized, so far as could be learned.

Of the above mentioned 362 abnormal stomachs, 122 were in men and 240 in women. Almost exactly two-thirds were thus in the female sex and only one-third in males. Of the displacements, in which the whole organ had descended instead of a part only having been stretched downward, the disproportion is still more striking. There were eighty of these, of which only twenty were in men, and sixty, or just three times as many, in women. This is in spite of the fact that nowadays, in cities at least, outside of the laboring class, a large proportion of men take scarcely more exercise than women, and all classes of men abuse their stomachs far more generally by the pleasures of the table and the temptations of the drams shop. The conclusion is inevitable, therefore, that the great preponderance of this trouble in the weaker sex—weaker mainly because of their hygienic faults—is due largely to the harmful modes of dress prevalent among them. The constricting corset not only limits respiratory movements and tends by its direct compression to force several of the viscera inward and downward, but also keeps the lower thorax and entire abdomen of the wearer in splints even when not very tightly laced. In this way the muscles of the underlying region—precisely those whose function it is to help support the organs in place—are prevented from obtaining any efficient exercise, so that increasing flabbiness and atrophy of the abdominal walls ensue as a matter of course.

Further, the heavy dragging skirts, unsupported in the case of most fashionable ladies except by pressure upon the ever-weakening trunk muscles, with some help from the projecting hips, exert, whenever the victim is on her feet, a continual downward traction upon both the relaxing walls and yielding contents of the abdomen.

In view of these conditions the only wonder is that any woman who has conformed to the requirements of fashion during the years of adolescence (when the structures involved are especially pliant and easily pressed or stretched away from the normal), is to be found with healthful abdominal organs in their proper positions. And since many more young men than formerly, especially soldiers, militiamen, and the cadets in the numerous military schools, have taken to holding up their trousers with tightly buckled belts, which are only less injurious than corsets, we may expect to meet in the male sex with a larger crop of displaced organs by and by.

The statements contained under the foregoing five heads embody facts familiar to most physicians who have done much special work in diseases of the digestive system, though one or two of the points are not yet fully admitted by all. Our gynecologic friends, advancing steadily and triumphantly upward from their original habitat in the pelvis, have reached the regions of the appendix and the kidneys, which they already claim as their own. Edebolhs, who is one of the ablest of them, and a few other brilliant operators of like enthusiasm, virtually insist now that any woman’s alls that refuse to yield to a removal of the ovaries and tubes, uterus and appendix, must certainly be cured by anchoring in position any kidneys that they may find to be movable. These gentlemen do not seem to have yet reached a practical realization of the fact that dilated or displaced stomachs, which are nearly always associated with loose kidneys, are very often the principal cause of the seriously impaired health which results from the general atony and giving way of all the intra-abdominal organs. Yet these abnormalities require treatment quite as much as, and usually far more than, the movable kidneys. Indeed, the same gentle measures that will in time commonly restore the atonic and displaced stomach and intestines nearly if not quite to
the normal, often overcome the mobility of the kidneys; and when they fail it is time enough to operate. Yet Edebohls in his recent papers does not show any appreciation of the fact that in these complicated cases anything is necessary except to do a nephrohraphy for the kidneys, and then, upon occasion, remove the appendix for the chronic appendicitis which he holds often results from, and "may be the only symptom of movable right kidney," a new doctrine which is, to say the least, by no means proved.

Since writing the foregoing part of this article I have read Dr. W. Gill Wylie's paper on "Anemia as Observed in a Gynecological Clinic, etc.," which appeared in the Medical Record of May 20. It is gratifying that this most distinguished gynecologist freely admits the only important point I have made here, which there seemed any likelihood of being disputed—that is, that ptosis of the stomach and colon is a frequent cause of uterine displacements. Referring to cases of "melancholia, hysteria, hypochondria, etc.," he says: "These cases are frequently associated with relaxed abdominal organs when there are loose kidneys, ptosis of stomach, with omentum and intestines crowding down in the pelvis on top of a retroverted or flexed uterus, and the patients have been treated indefinitely with pessaries for falling of the womb," etc.

In the same paper Wylie also discusses cancers and ulcers of the stomach and intestines, constipation, chronic appendicitis, obstruction of the gall-ducts, chronic colitis and proctitis, etc., as causes of anemia, and his method of treating constipation especially, all of which proves that he is developing rapidly into an able and skilful specialist for diseases of the entire digestive system. Verily the gastroenterologists are in danger of finding their occupation gone.

The general surgeons, also, are turning to the digestive organs as a fruitful field, and are already pulling up and stitching in place prolapsed stomachs and taking tucks in dilated ones. There are, indeed, conditions in which these new operations may be indicated, though most cases of the kind are curable by non surgical methods. When the pylorus is obstructed by a tumor, the cicatrix of a healed ulcer, or other cause which is insuperable by milder measures, or in persons who cannot afford either the time or expense of prolonged treatment by massage, gymnastics (or sometimes a period of rest in bed), intra-gastric electricity, etc., required to effect a cure, it is entirely proper to invoke the aid of the surgeon. Let us, also, render a full tribute of praise to the untrining energy and genius of the men who have wrought such marvelous results in abdominal surgery in these latter days—especially our American confrères, who now stand unsurpassed in their line. But at the same time it is just that the equally beneficent and often life-saving work now being done in this region by far less dangerous, even if less rapid and brilliant, methods should be given its proper meed of recognition. The gastroenterologists of the United States, though yet comparatively few in numbers and lacking in efficient organization, are achieving here and there, individually, results which have not yet commanded from the profession at large the attention they deserve.

Edebohls puts forward the claim, supported by the dictum of Glenard, that though there may be cases of movable kidney without enteroptosis, there can be no enteroptosis without movable kidney. This statement, notwithstanding the high authority from which it emanates, will not bear the test of clinical experience. Most of the special workers in this field see cases that disprove it. My own records alone show numbers of such. Two of the three cases reported below had gastroptosis without nephroptosis.

CASE I.—A married lady, aged fifty-six, consulted me September 20, 1898. Her weight then was 92 pounds, and she had been in ill health for several years, complaining particularly of her stomach. She had had the best of medical advisers before, but had never been examined by a stomach specialist, and the only diagnosis reached, so far as she knew, was dyspepsia and nervous prostration. Her worst complaint was a "sore, tired, distressed feeling in the pit of the stomach and a constant dragging sensation when on her feet;" also great weakness, a poor appetite, and constipation. She had passed the menopause eight years before. The examination after inflation with CO₂ showed a marked prolapse of the entire stomach "with dilatation, the lesser curvature being just below the lowest ribs, and the greater curvature four inches below the level of the umbilicus. The liver was enlarged decidedly, and the heart was somewhat hypertrophied, the area of dullness extending to the nipple line and the apex beat being found in the same line. The kidneys were in normal position, as demonstrated by repeated careful examina-
tions. Transverse colon pushed downward below stomach. Other organs negative. Analysis of stomach contents showed a slight excess of hydrochloric acid, but fortunately not enough to contraindicate abdominal massage. The treatment consisted of a bland and easily digestible diet, special exercises for the abdominal muscles, a special abdominal supporter containing springs which exerted strong upward pressure; full massage, including deep kneading of the abdominal region; galvanism from spine to solar plexus, and also over the course of the pneumogastrics in the neck. Her skin was sallow, almost cachectic, and her countenance showed mental depression. The urine contained an excess of indican. She received in the way of medicine strychnine and hypophosphites for a part of the time, and a mixture of nuclein and bone-marrows later. The Drysdale aperient was given for the bowels. This was a very exceptional case, in that the stomach could not be trained to tolerate a tube or even the fine rheophore of an intragastric electrode, and therefore intragastric electricity, one of the most efficient remedies at our command, could not be given.

October 6. Her appetite has come up, and the dragging sensation is much relieved.

November 14. Still weak, but has gained five pounds. Scarcely any discomfort now. Lower border of the stomach one and a half inches below the umbilicus.

November 21. Stomach extends to umbilicus only. Area of liver dulness normal. No more dragging or distress in stomach. Appetite better.

December 27. Feels much stronger and better. Can walk eight squares now without getting tired.

January 24. Still improving; stronger; better color, and good sleep.

At the last examination, made shortly after this, her stomach had come up so far that the lower border was entirely above the umbilicus. She had not fully recovered her normal weight and color, but felt so well as compared with her former condition that she could not see any necessity for continuing treatment longer.

The two following cases exemplify further what can now be accomplished without surgery. My records contain scores of cases of Glenard's disease in which not only have the symptoms been either removed or markedly ameliorated without the help of the knife, but also in many of them the prolapsed stomachs have been gradually brought up to nearly their normal positions (as in Case I above), and the dilated ones, when not due to obstruction, have almost uniformly been contracted until the greater curvature has been brought well up above the level of the umbilicus. Occasionally even the loose kidneys have ceased to be movable or even palpable, and when this failed to be accomplished the pain and tenderness in the affected kidneys in nearly all the cases have been wholly relieved.

Case II. — Unmarried lady aged twenty-three; came under treatment January 17, 1899. Always well until the previous April, when she had scarlet fever, and following that, according to her own statement, albuminuria. This disappeared two weeks ago. For half a year past she has complained very much of morning nausea, with occasionally nausea all day. Menses irregular of late and very painful. Always very constipated; often several days without a stool. Does not take laxatives except very rarely. Much flatulence, the gas passing freely both ways. Used to ride a wheel, but could not now, being too weak. She was extremely thin in flesh and very anemic. Examination showed liver enlarged slightly, lungs normal, and heart enlarged about one inch to the left; apex beat also too far to the left. Stomach dilated from normal above to two inches below the level of the umbilicus. Uterus anteflexed and very sensitive to the touch. Left ovary also sensitive, though not appreciably swollen. Much leucorrhea. Findings otherwise negative. Analysis of the stomach contents after Ewald test breakfast showed a total acidity of 40, but no free hydrochloric acid by the Mintz method, and a small amount of mucus. The urine was found normal by repeated examinations, except that there was an excess of triple phosphates.

The treatment included faradism applied directly to the inner walls of the stomach by means of my improved intragastric electrode, massage, special exercises for the abdominal muscles, reform dress, and tonic medication, including especially hydrochloric acid and pepsin; also a careful but regular use of mild laxatives. The result was fortunate in spite of a severe and stubborn attack of influenza which came on during the treatment, and of a pending marriage engagement with its disturbing influence. She was well enough to discontinue active treatment early in April, and my last entry showed the lower boundary of her stomach to be one and a half inches above the umbilicus; and liver and
heart both within their normal limits. Her bowels were regular without laxatives, and all nausea had disappeared.

Case III.—Lady aged thirty, married six years but never pregnant, consulted me September 14, 1898. The chief complaint for which she desired relief was a pain alleged to be in the region of the right ovary, and for which she had received treatment for vaginismus off and on for five years. She had indigestion after sweets or fried things, and suffered from dizzy spells. She was also nervous, often constipated, and had a sallow complexion.

Examination showed nothing abnormal in the pelvis, except that the uterus was inclined slightly backward. No swelling or sensitive spots in the adnexa. Liver, heart, and lungs were normal. The stomach was dilated to one inch below the umbilicus, and a light, non-nitrogenous luncheon was not yet out of it at the end of three hours, showing bad motility. Splash pronounced even before drinking anything. Right kidney quite movable and also tender. The appendix was also slightly thickened and tender. The stomach contents after the Ewald test breakfast showed no free hydrochloric acid, but a total acidity of 38; some gastric catarrh.

Treatment: Abdominal supporter, faradism with my intragastric electrode, abdominal exercises, massage, lavage, laxatives, and tonics, including hydrochloric acid and peptone.

Result: December 23 she reported that she felt as well as she ever did, and though all her faulty organs were not anatomically correct, she could not afford to go on with treatment. Her stomach then extended to one inch above the level of the umbilicus instead of an inch below as at first; it emptied itself in about the normal time. There was no longer complaint of pain in the region of either the appendix or the right kidney, which was still somewhat movable. She was symptomatically well, and her gastric dilatation was virtually cured.

Most of the points already made are strikingly confirmed in a recent paper by Stengel and Beyea.* They report very fully a case occurring in the practice of the late Dr. Wm. Pepper, which was carefully studied by him and by Dr. Stengel. It was that of an unmarried woman of twenty-five with an extreme degree of splanchnopsis, the stomach having been displaced to within one and a half inches of the pubes, the intestines also displaced downward, and the right kidney dislocated and movable. No reference was made to the condition of the pelvic organs or appendix. There was no history, the authors say, of traumatism, illness, nor of abdominal distention by pregnancy or fluid effusion, to explain the displacement, and they state that “the cause, therefore, must be considered as most probably compression of the thorax by tight clothing and relaxation of the ligaments.”

A nephrohrhapsy was first skillfully done by a prominent surgeon and was without marked results, though usually this operation is followed by relief of the symptoms due to the renal mobility. The right kidney continued to be palpable, below its proper position, and often painful. The flatulence, constipation, and other severe gastrointestinal symptoms persisted. The enormous gastropiosis continued, and the organ even increased in size after the nephrohrhapsy. A year later, in April, 1898, Dr. Beyea did an ingenious operation to bring up and hold the stomach in place. Tucks were taken in the gastrophrenic ligament and in the gastrohepatic omentum. Nine months later the patient was found to have gained in health and weight, and by the end of thirteen months she was decidedly better in all ways. Examination showed the greater curvature one and a half inches below the level of the umbilicus.

This was a very creditable result for so bad a case, but it is worthy of particular notice that it was not so favorable a result as was obtained in my Case I, in which non-surgical methods only were employed.

In addition to the five propositions laid down in the beginning of this paper, which can be proved beyond question if not already sufficiently well established, a few further important conclusions are fairly deducible:

1. The fact that over one-half the patients examined at my offices during a period of about three years suffered with displacement or dilatation of either one or several of the abdominal organs, shows the enormous frequency of these serious diseased conditions—a state of affairs little understood or appreciated by the profession at large.

2. The fact that, in so far as the patients or their friends were aware, not more than one per cent of the large number of 362 displacements and dilatations of abdominal organs had been previously diagnosed,

---

*“Gastropiosis; Report of a Case in which a New Operation was Undertaken and the Patient Greatly Improved,” American Journal of the Medical Sciences, June, 1800.
indicates an extraordinary indifference to this important class of cases on the part of physicians generally.

3. There is a deplorable lack of knowledge of what can be, and is being, done in abdominal displacements and dilatations by simple, safe, and efficient, even though often tedious, non-surgical methods.

There seems to be a prevalent impression that physicians who devote themselves to the diseases involving the digestive organs are occupied chiefly with washing out stomachs and testing gastric contents for hydrochloric acid. Manifestly it behooves such specialists to let the real truth be known more widely, in the interests both of conservative medicine and of humanity.

A NOTE ON THE EMPLOYMENT OF SOLUTIONS OF TOLUIDIN-BLUE IN EXTERNAL INFLAMMATORY DISEASES OF THE EYE.*

BY CLARENCE A. VEASEY, A.M., M.D.,
Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic; Demonstrator of Ophthalmology, Jefferson Medical College, etc.

In the Philadelphia Medical Journal of August 13, 1898, the writer called attention to the use of solutions of toluidin-blue in the treatment of the external inflammatory conditions of the eye. At that time he had been using these solutions with excellent results for about six months in most of the cases coming under his observation, and since then a much more extended experience has given no cause to change the conclusions then formed.

Inasmuch as some of the members may not be acquainted with the drug, the writer may be pardoned for repeating that it is a bluish crystalline powder, soluble in alcohol or water, and according to Merck, "is prepared by oxidizing a mixture of thiosulphonic acid and orthotoluidin with a chromate to an insoluble sulphonide-acid green, then boiling the latter with a zinc chloride solution, and subsequently oxidizing the leuco-compound. While considered a zinc chloride double salt of dimethyltoluethionin, its composition shows it to be a hydrochlorate."

The strength of the solution that has given the best results, and proved the most satisfactory, is 1 part in 1000. Solutions of varying strengths, from 1 in 10,000 to 1 in 20, have been tried, but the stronger solutions produce a much more intense stain of the tissues and surrounding skin, and do not appear to be any more effective than the solution of the strength of 1 in 1000. The strongest solutions that were tried did not produce any irritation.

In the early experiments the solutions of toluidin-blue were employed alone to flood repeatedly the conjunctival cul-de-sac in the manner that is customary with solutions of boric acid, but later experience showed that it was just as effective to cleanse the affected part first with some cleansing lotion—say boric acid or salt solution—using it with sufficient force to get rid of the accumulated secretions, and then to flush thoroughly with the solution of toluidin-blue, and after it has remained in contact with the parts for a while to wash off the excess with the boric solution. As every particle of mucus or muco-pus is stained a deep blue, none can remain on the conjunctiva without being detected. The stain on the fingers and surrounding skin is readily removed with a moist pledget of absorbent cotton.

As to the frequency of making the instillations, the writer has been guided in a given case by the custom of using other applications—the more copious the discharge, the more frequently the instillations have been made.

The solutions have been employed in the different varieties of conjunctivitis and seemed to be of special value in those varieties accompanied by marked discharge, such as the acute contagious and the purulent, the discharge after a few applications becoming markedly lessened. In connection with its employment in purulent conjunctivitis I am told by one of my former clinical assistants, Dr. A. H. Read, who at my suggestion tried it for urethral irrigations in gonorrhea, that it produced very satisfactory results. In corneal ulcers and abrasions, it not only promotes the reparative process, but, as was pointed out in the previous paper, stains them a deep blue (in this respect being similar to the green reaction of fluorescein), thus enabling one from day to day, at the time of treatment, to note the progress in size.

In purulent dacryocystitis the results are equally good. In recent uncomplicated cases the writer has seen the almost entire cessation of discharge after a few thorough washings. Experience has shown that it is better to cleanse the duct with the boric or saline

* Read by title at the meeting of the Pennsylvania State Medical Society, at Johnstown, May 17, 1899.
solution first, and then to follow with copious irrigations of the solution of toluidin-blue. If the solution does not regurgitate into the conjunctival cul-de-sac or drip into the nose, it is allowed to remain in the duct. If, however, there are some sinuses or pockets, in which the solution has accumulated and from which it is constantly oozing, either from the canaliculus or from the nasal duct, it is better to follow the toluidin-blue irrigations with some colorless solution.

This note is presented in the hope that other members of the Society will test the drug in their own work, not only in inflammatory conditions of the eye, but in other conditions accompanied by discharge and requiring a cleansing and stimulating wash, and report to us the results of their experience.

TREATMENT OF SUMMER DIARRHEA IN INFANTS.

BY DAVID BOVARD, JR., M.D., NEW YORK,
Pathologist to the Foundling Hospital; Attending Physician to the Seaside Hospital of St. John’s Guild; Assistant to the Chair of Pediatrics, University and Bellevue Hospital Medical College.

In discussing the treatment of these conditions we shall do well to bear in mind the exciting causes and the pathological lesions which underlie them. We are fairly well agreed that the chief factors in the production of summer diarrheas in infants are: (1) improper food; (2) increased heat; (3) foul air, and like unhygienic conditions. With reference to the pathological findings we are often puzzled and confused by the variety and extent of the lesions found in the gastrointestinal tract and the apparent lack of harmony between the clinical history and the results of autopsies. Doubtless the difficulty here lies in the fact that our ordinary autopsies do not bring out one very essential feature of these cases—the presence of great numbers of bacteria and the toxins produced by them. Suffice it to say here that we regularly find a simple catarrhal inflammation of the mucous membrane of a greater or less portion of the gastrointestinal tract; that the stomach, lower part of the ileum, and colon are the parts most affected; that the changes are usually more marked as they advance down the intestine; and that we rarely see any lesion more severe than a necrosis and exfoliation of the superficial epithelium of the mucous membrane. Added to these tissue changes we have the presence of great numbers of bacteria, not of one but of many kinds, and the toxins that are produced by their growth.

With these points before us we may take up the question of treatment to better advantage.

1. Prophylaxis.—Much has been done, but more remains to be done, in this regard. The food of infants—i.e., children under two years—during the summer months at least should consist of milk alone. That milk, when given, should be fresh and free from the bacteria that may do harm. Fresh milk can ordinarily be had by any careful person, but to make sure of the second point it is necessary, as a rule, to subject the milk either to sterilization by boiling or to Pasteurization. Of the two methods the latter is doubtless preferable where it can be properly carried out. If there is uncertainty about it, we had better advise boiling the milk during the summer months. Furthermore, having secured a pure and sterile milk, it seems advisable to the writer to counsel moderation in the use of it during the danger season. We have lately been so thoroughly instructed as to the rate at which an infant should gain by week and month, and the quantity and proportions of the milk required to secure this result, that some of us forget that we are not dealing with a machine, and continue to feed during the summer without regard to the natural inclination to take less food, both in quantity and quality, during this time. Only when the baby suddenly becomes ill do we realize our error. It is impossible to give a general rule, but we ought to treat an infant much as we would like to be treated with respect to summer food.

As far as possible, children ought to spend the summer in the country, but the great majority in our large cities must still endure, as best they may, in their miserable homes. Here and there in New York a small breathing spot of a park has been opened in the midst of many acres of stifling tenements. The little done only emphasizes the need of more. Recreation piers have also afforded some slight relief, and we are even making through the Tenement House Commission a little attempt to strike at the root of the evil by reforming the construction of the homes of the poor. The mind of the community is only slowly awakening to the needs of the children, but there are some hopeful signs of progress.

2. Treatment.—First of all, whatever the food the child has had, stop it. I am a thorough believer in the policy of "bold
starvation." I believe that in most severe cases we would do well to give nothing but water for twelve, twenty-four, or even forty-eight hours.

When feeding is begun, it is best to use some liquid food which can leave no irritating residue in the stomach or intestine. For this purpose such preparations as rice- or barley-water, or whey, etc., are of service. Even these should be given in small quantities and at definite intervals. During the early days there is much more danger of feeding too much than too little. Only when the acute symptoms have subsided and there is a decided improvement, marked by lessened temperature and a gain in strength, is it proper to begin again the giving of milk. This should be given only in very dilute form and in small quantities at first. There is no more difficult problem in infant feeding than that of giving milk to an infant just recovering from diarrhea. With very young infants the milk should be diluted till both fats and proteids are one per cent or less, while four or five per cent sugar may be given. The strength of the food can be increased gradually as improvement occurs. If the administration of milk brings an increase of the fever or diarrhea, it should be diluted still further or discontinued for a time. All the milk given should be either Pasteurized or sterilized.

In the beginning of treatment, after having stopped feeding, the alimentary tract should be cleared out thoroughly. This can be accomplished by washing out the stomach, giving calomel in small doses (gr. $\frac{1}{4}$, every hour for eight or ten doses) to empty the small intestine, and employing rectal irrigation to serve the same purpose in the colon. If vomiting persists after this initial clearing, the stomach washing may be repeated, but as a rule this is not required. The irrigation of the colon should be repeated two or three times a day, so long as fever continues. If water, or better, salt solution at a temperature of $85^\circ$ to $90^\circ$, be used, the irrigation will have a favorable influence not only by reason of its cleansing effect, but by reducing the temperature. Care should be exercised in employing irrigation not to make the water so cold or the process so prolonged as to produce marked depression. Unless a competent nurse can be secured, the irrigation should be done under the personal supervision of the physician.

If the temperature is very high, either sponge or tub baths should be regularly employed for its control. The temperature of the bath should be the same as for the irrigation. The time should not exceed ten or fifteen minutes, and, as with irrigation, care should be taken not to produce too great depression. Whiskey or brandy, well diluted, should be given either with the bath or immediately after it to prevent this.

Apart from its use with the bath, alcohol in either of the above forms should be regularly given in all cases of marked prostration. It should be diluted from six to eight times and given in small doses frequently repeated. In these diarrheal diseases of infants it is as much our mainstay for systemic stimulation as in the typhoid fever of adults. There is no adequate substitute.

The only other medication which can be unreservedly commended is the use of bismuth in large doses, ten grains every two hours. The familiar subnitrate is as good a preparation as any. To overcome the difficulty of giving such a bulky powder to an infant, it is best to suspend it in mucilage.

To recapitulate the points of importance. We are dealing with an acute inflammation of the gastrointestinal tract, accompanied by more or less systemic infection produced by the presence and activity of bacteria. We aim to treat the inflammation by rest. Rest is secured by first withholding food, washing the stomach, emptying the small intestine by medication, and irrigating the colon. Then for a time we give foods that will leave little or no residue, and only very gradually and carefully return to the use of milk. Further, we endeavor to limit the action of bacteria in the intestine by the internal administration of bismuth and the systematic use of irrigation of the colon. Finally, we counteract the systemic infection by the use of cold baths and the administration of alcohol.

Recognizing the influence of high temperature and foul air in the production and maintenance of these summer diarrheas, certain of our charitable organizations have sought to give relief to the little patients by providing hospital boats on which they may be carried from the heated air of the city to cool breezes of the sea, while at the same time they receive the attentions of skilled physicians and nurses. Lately seaside hospitals have been added for the reception and care of the more desperate cases. The results thus far have been most gratifying and serve to indicate still more emphatically the need of improvement in the surroundings of the poor at home.
A PRELIMINARY NOTE ON THE USE OF ASPARAGUS AS A DIURETIC.

By H. A. Hare, M.D.,
Professor of Therapeutics in the Jefferson Medical College, Philadelphia.

The well known fact that asparagus tops when they are eaten usually produce free diuresis would indicate that the plant might be used as a diuretic in cases in which the urinary flow is scanty. I am well aware that in so using it I have by no means done anything original, but a somewhat intimate acquaintance with therapeutic literature and practice has not brought me in contact with its employment. At the time I began using this plant for the purpose named, it was not possible for me to obtain a fluid extract made from asparagus tops, but Parke, Davis & Company placed in my hands a fluid extract made from the root stalk, and it is with this preparation that the tests here recorded have been made. The same firm has kindly made an extract from the tops, which I am at present testing.

The first case in which I tried the drug was that of M. C., a man of thirty-five years, who was suffering from cirrhosis of the liver with swelling of the ankles and legs, and secondary gastric disorder with nausea. A month before he came under my care he noticed that his abdomen was beginning to swell, and he had a "smothered sensation" when lying down, probably due to the ascites. An examination of his urine revealed marked albuminuria, the albumin being "one-third," but no sugar. The microscopic examination was practically negative. Under careful treatment with rest in bed the edema became much improved, but after reaching a certain point no gain was made. The urine being measured every day, it was found that the daily amount varied from thirty-five to forty-eight ounces during a period of fifteen days. On the sixteenth day a drachm of the fluid extract of asparagus three times a day was administered. In the next twenty-four hours the daily amount of urine rose from thirty-nine to sixty-two ounces, and five days later reached seventy ounces and remained almost as profuse as this, varying from fifty-five to sixty-five ounces for the next twelve days, after which time the drug was stopped, with the result that the quantity of urine gradually fell to between thirty-five and forty-five ounces in the twenty-four hours. After a lapse of nine days the asparagus was given a second time, and the quantity of urine at once rose in the first twenty-four hours from forty to forty-five ounces, then to fifty ounces, and then to sixty-three ounces. The quantity remained at from sixty-three to fifty ounces for one month, during which time the drug was continued. It was again stopped, and as before the quantity of urine fell in four days to forty ounces. Under the treatment the dropsical symptoms disappeared.

In another case under observation a shorter time, the condition being one of disordered digestion and marked edema of the legs resulting from a double mitral lesion, and in which only twenty to twenty-five ounces of urine was passed in twenty-four hours, the use of digitalis with bitartrate of potassium failed to produce any diuretic influence. The bitartrate was then replaced with infusion of juniper berries and acetate of potassium, a pint a day, without effect. Fluid extract of asparagus was then given, and the urine in the course of three days rose from twenty-seven to forty ounces, and remained at thirty-five to forty ounces while the drug was continued. In a case of advanced atheroma with aortitis and probably fatty heart, no marked effect was produced by the asparagus.

THERAPEUTICS OF SUMMER DIARRHEA.

By C. G. Jennings, M.D.,
Detroit, Michigan.

The preventive treatment of the summer diarrhea of infants demands the most careful supervision of the diet and the whole hygienic influences surrounding the child during the hot months. As Seibert, of New York, has observed, summer diarrhea becomes epidemic whenever the average minimum temperature reaches 60° F. During the colder months even badly fed city infants do not suffer seriously from diarrheal diseases. They may suffer from malnutrition and continuous indigestion, but diarrhea does not frequently menace their lives. It is the summer heat that is the important etiological factor in the production of summer diarrhea. The high atmospheric temperature acts to produce diarrhea, first, by debilitating the infant's digestion and general nutrition, and secondly, by favoring decomposition in the infant's food. Nursing infants escape because they are, as a rule, well nourished and resistant, and because their food is easily digested and is sterile. Artificially fed infants, as a rule, habitually digest badly and
only exceptionally are perfectly nourished, and their food is digested with difficulty and frequently infected. The summer heat that diminishes still further their powers of resistance favors the growth of saprophytic and other microbes in the milk that is their food, and the higher the temperature the feeble their resistance, and the more rapid and toxic the milk decomposition.

The principles of the prevention of summer diarrhea are to keep the infant's nutrition and digestion up to the highest possible standard, and to administer during the heated term a sterile food so modified as to suit the enfeebled infant's digestion. Whenever possible artificially fed infants should spend the summer in the country, away from the overheated and microbe-laden city air. When compelled to remain in the city, they should have all the out-of-door air possible. A few hours each day under the trees, in shady streets or parks, will do much to improve their condition. Their clothing should be suited to the temperature. When this approaches 90°, a single light garment, with additional abdominal covering, will keep them comfortable. Frequent tepid bathing is of the greatest value. During the heated part of the day older infants and children may be given a tepid or cool tub. They may be allowed to paddle in the water for one-half hour or more, and the bath may be repeated in the evening should the heat continue. Cool sponging is often better for very young and feeble infants. The tonic and refreshing influence of a cool bath on a hot day is familiar to all.

The details of domiciliary hygiene are not always under the control of the physician, but he should do his best to improve them. Perfect cleanliness of the infant and its surroundings is of the greatest importance, and the most exquisite care of the food and food utensils is essential. During the hot months milk given to infants should be sterilized by boiling for from fifteen to twenty minutes. With a remote milk supply, pasteurization cannot be depended upon. Whatever objections there may be to sterilized milk are outweighed by safety from infection that sterilization brings. In the country, or where milk can be obtained within an hour or two of the milking, one meal of fresh milk may be given. The milk for all other meals should be sterilized.

Clinical experience has confirmed the teaching of a number of authorities that one of the cereals added to an infant's milk will frequently aid its digestion, and infants during the latter six months of the first year will often show improvement in their digestion and nutrition when a small quantity of a thoroughly cooked cereal is added to their food. Barley-water, oatmeal-water, thin arrowroot gruel are accessible in all homes and are useful diluents. In exceptional and difficult cases one of the farinaceous patent foods of the market may serve where home products fail, and in others a good Liebig's food with the starch transformed into dextrin and maltose may serve an excellent purpose.

The summer diarrhea of infants is an acute gastroenteric infection—acute milk infection. The symptoms are due to the absorption of poisons generated in the stomach and intestine by putrefactive decomposition of their contents. This condition is a frequent sequel to an attack of acute indigestion. In certain cases the intensity and duration of the poisoning develop structural changes in the ileum and colon. The case becomes an enterocolitis. In others the toxemia is profound. The heart, the nerve centers, and the vasomotor nerves suffer severely from the intoxication, and the clinical picture is one of cholera infantum.

Summer diarrhea being then a gastroenteric intoxication, the indications for treatment are: first, to remove as quickly as possible the toxic materials from the alimentary tract; secondly, by appropriate dietetic and medicinal means to limit further elaboration of poisons; thirdly, to combat the symptoms resulting from the intestinal intoxication.

As in the treatment of every intoxication due to the absorption of the products of decomposition from one of the cavities of the body, promptness and thoroughness of action are essential. Immediately upon the development of symptoms of gastroenteric infection, vigorous eliminative treatment should be begun. To delay is to risk the development of an uncontrollable toxemia or the onset of grave anatomical changes in the intestine. Every acute indigestion in an infant during the hot months should receive prompt attention. The habit of looking lightly upon an apparently mild indigestion diarrhea cannot be too strongly condemned.

The first indication is to empty as quickly as possible the stomach and bowels. The colon should be irrigated every two to four hours until the whole of the intestinal tract is emptied. In the beginning of the attack
the stomach also may be washed out, although this measure is not so often necessary. With the irrigation of the intestine a cathartic dose of calomel and soda may be given—one-tenth grain of calomel with one-half grain bicarbonate of soda every hour for five doses. For intestinal irrigation warm normal saline solution is best; it is non-irritating, and being quickly absorbed from the bowel adds to the circulation the fluid that should be taken up from the stomach. When fever is high, the temperature of normal saline may be reduced to 95° or 90°.

Administration of food by the stomach should be stopped at once, and no food should be given for from twelve to twenty-four hours, or until there is a decided improvement in the intestinal symptoms. Mothers object to this rigorous treatment, but it is essential to a perfect success.

When the stomach will retain it, water should be given freely. After the first twenty-four hours, careful feeding may be begun. Milk should not be given until the child is well on the road to recovery; in the place of milk, a thin cereal gruel, diluted beef juice, whey, a thin solution of one of the malted foods, delicate beef, chicken, or mutton broth. Food should be administered in small quantities frequently—one or two ounces every two hours. In feeble children and in cases showing severe toxic prostration, the addition of two to three drachms of whiskey or brandy in the twenty four hours acts well. As the condition improves, milk may gradually be added to the food. It should be given at first plain, diluted five to six times with a four-per-cent solution of milk-sugar. By this dilution is made a mixture low in fats and proteins, but containing about four per cent of carbohydrates. Medicines for the control of the diarrhea are of secondary importance. After the bowels have been thoroughly emptied—not before—and particularly if there be pain and tenesmus, opium carefully given is of great benefit. A child of one year may be given ten drops of paregoric or one drop of chlor anodyne after each movement. By this means as the movements diminish in number the opium is decreased. The opium always should be given alone. When symptoms of lower bowel irritation are prominent, a starch enema containing two to six drops of laudanum is an efficient measure; it may be given after each movement. Internal intestinal antiseptics are disappointing, although occasionally they may do good. Bismuth sub-
nitrate in full doses, ten to fifteen grains, suspended in an aromatic water, may be given every two hours. To this may be added, when evidences of fermentation continue, half a grain of either carbonate of guaiacol or salol.

In many cases grave toxic symptoms are prominent. The temperature rises to 104° or 105°, the child is restless, drowsy, often comatose, and there are all the indications of a profound toxemia. For these symptoms, no measure with which the writer is acquainted is so efficient as the bath. In young, feeble, and prostrated infants the temperature of the water at the beginning of the bath should be about 100°. It may be gradually cooled during the course of from eight to ten minutes to 90° or even 85°. The effect of such a bath upon these children is often magical, and before the bath is ended they will arouse from their stupor and begin to play in the water as they are accustomed to do when well. The bath may be repeated every two, four, or six hours, depending upon the range of temperature and the intensity of other toxic phenomena. With the thorough use of water internally and externally, opium and other sedative and astringent drugs will rarely be necessary.

As convalescence is established the greatest care is necessary in the adjustment of the food to suit the gradually strengthening digestive power of the infant. Its appetite is frequently far beyond its power to digest, and the mother must be most carefully instructed as to the quantity and quality of the food. Relapse must be carefully guarded against, and the occasional administration of a gentle laxative like calomel will be most efficient in preventing it.

Rupture of the Popliteal Artery.

Meyer (Deutsche Zeitschrift für Chirurgie, 51 Bd., 3 u. 4 Heft, Leipzig, Vogel, April, 1899) reports a case of subcutaneous rupture of the popliteal artery, which was accompanied by neither swelling nor tension of any kind in the popliteal region. The diagnosis was made only when gangrene of the foot developed. It follows from this that whenever an injury has been inflicted in the popliteal space pulsation of the tibial artery should be felt for. In case this is absent, and especially if anesthesia and subnormal temperature develop in the foot, the proper therapeutic measures should be taken before gangrene develops.

COLLATERAL TREATMENT DURING THE ADMINISTRATION OF THYROID EXTRACT.

It is a well known fact to those who have used thyroid gland in the treatment of the various pathological conditions which indicate its use, that it is a substance capable of producing, when given in fairly large doses, very distinct evidences of its physiological activity, represented chiefly by exaggeration of the heart's action, irregularity of the pulse, and other circulatory symptoms, which are not only disagreeable to the patient but are actually capable of serious consequences. At the same time, under its influence, there is usually, is claimed, an increase in the oxida-
tion process in the body, and it is sup-
pended that by this means thyroid medication does good in obesity. In some instances in which the administration of the gland is followed by excellent results, we are prevented from administering it in large quantities by reason of these symptoms, therefore we regard with interest a communication recently made by Mabille in Les Nouveaux Rémedes of May 8, 1899. This author asserts that he has used arsenical preparations for the pur-
pose of antagonizing thyroidal intoxication with excellent results, and he believes that these results are obtained through the ener-
getic restraining influences of arsenic upon oxidation processes, and that this administra-
tion also diminishes the palpitation of the heart without in any way interfering with the other good influences of the thyroid gland.

Before relying the arsenic clinically Mabille carried out a series of experiments upon dogs and rabbits, administering to them thy-
roid gland and Fowler's solution. He found that his theoretical views were supported by these experiments, and when he tried them clinically he also found good results; or, in other words, that he was enabled to push the thyroid gland in ascending doses more rapidly and with better effect when arsenic was given than without it.

It seems to us that this is an interesting field for clinical research, and we hope that Mabille's experiments may be tested and found correct.

TREATMENT OF SURGICAL SHOCK.

We have from time to time pointed out in the pages of the Therapeutic Gazette the necessity of considering the condition of the vasomotor system in the treatment of diseases, and we constantly state to our classes that in the treatment of surgical shock, or collapse occurring during the course of nonsurgical diseases, it is of vital importance not only that we stimulate the heart, but also that we maintain arterial tension, directing our attention to the condition of the vasomotor center and the blood-vessels which it sup-
plies. We believe that many of the fatalities of disease are due to this condition of vasomotor relaxation, and therefore we have read with much interest the results obtained by Crile, of Cleveland, in certain experiments which he has recently made in regard to the pathology of surgical shock. This vasomotor effect is probably the reason why Crile has found that operations upon the abdominal area and the regions of the duodenum, pylorus, and gall-bladder are the most apt to produce this condition, since the vascular system of this neighborhood is capable of containing all the blood in the body.

One of the most important results of this research is the indication that surgical shock is mainly due to the impairment of activity of the vasomotor mechanism. Crile's research
therefore confirms the views we have already named, and those which have been so ably advanced by Mr. Leonard Hill, of England. It seems to us, too, that these studies do much towards supporting the views we have already expressed concerning the influence of chloroform in producing death by vasomotor paralysis.

**THE ERUPTION PRODUCED BY THE BROMIDES AND IODIDES.**

We have called attention a number of times in the editorial pages of the *Therapeutic Gazette* to the fact that these two classes of drugs, and quinine, are substances capable of producing very curious alterations in the nutrition of the skin, and apropos of these remarks our attention has been called to an article in *La Presse Médicale* of May 24, 1899, by Malherbe, of Nantes. He reports an instance of bromide eruption which occurred in a young girl of twenty-one years, who was suffering from epilepsy. Her hereditary antecedents consisted of alcoholism on the part of her father, who however denied syphilis; the mother was neurotic, but otherwise presented no distinct pathological conditions. On the 15th of March, 1898, she consulted Malherbe for the first time, having developed a very large ulcer during the previous three months on the lower portion of the left leg; within the previous three days she had also developed a profuse acne eruption of the face. So intense were the lesions that it was at first supposed to be due to syphilitic manifestation, but this possible diagnosis was speedily given up.

The treatment consisted in the suppression of the bromide, the use of arsenical waters, with a milk diet, and, locally, a poultice made of potato to which had been added boric acid. The eruption speedily disappeared under this treatment, so that within a few weeks nothing was left in the area which had been involved save a brown pigment spot. The stopping of the bromide, however, resulted in the return of the epileptic manifestations.

Another case was that of a patient of forty-five years, who was receiving doses of iodide of potassium because of asthma and pulmonary emphysema, and who had never suffered from any syphilitic manifestations. This patient developed upon his right shin a patch of local gangrene of considerable size. Here, again, the diagnosis of the cause of the condition was at first obscure, but that it was due to the iodide seems to be proved by reason of the fact that as soon as this drug was stopped and the gangrenous spot locally treated healing speedily took place.

Treatment in this case consisted in the arrest of the iodide of potassium, washing the spot with hot borated water, and using an ointment composed of:

- Oxide of zinc, 15 grains;
- Salol, 30 grains;
- Vaseline, 1 ounce;

associated with absolute rest and a milk diet. Somewhat similar cases to this have been reported by Gemy in 1891 and by Panichi in 1897.

---

**THE EFFECT OF THE ENTRANCE OF AIR INTO THE VEINS.**

The original and editorial pages of the *Gazette* have contained from time to time during the last twelve years papers in regard to this very interesting subject. The general trend of literature has seemed to indicate that air embolism is by no means as dangerous a condition as our forefathers considered it, and also that in a certain number of cases where it was supposed to have occurred, the presence of bubbles in the cardiac cavities and elsewhere was really due to the development of gas produced by the bacillus *Aerogenes Capsulatus*. Still more recently the *Centralblatt für Chirurgie*, No. 11, 1899, has contained an article by Sternberg, in which he details two cases where air entered the veins and gained access to the heart during operations for the removal of tumors about the clavicle.

In the first instance a woman aged sixty-one years, with normal lungs and heart, was operated upon for malignant adenoma of the right lobe of the thyroid, when a short, loud, wheezing sound was heard, and a very loud gurgling accompanied each heart sound; the respirations became superficial and the pulse slow, but there were no further bad symptoms and the patient soon recovered. The cardiac gurgling sound ceased in a few minutes. The cause of the entrance of air was the tearing of the external jugular vein. Death occurred from pneumonia on the fifteenth day.

The other case was a woman of fifty-five, who was being operated upon for an adenoma of the right lobe of the thyroid, when a rhythmical, gentle, sucking sound was heard; symptoms of syncope came on, the heart beat loudly against the chest, and a loud gurgling
sound was heard, while the normal sounds were absent. This sound was so loud that it could be heard by bystanders. In this case artificial respiration, faradization, and massage of the heart were tried, and complete recovery ultimately ensued.

The writer of this editorial has in a number of instances seen air accidentally introduced into the veins of human beings with no evil effects ensuing.

THE SURGICAL TREATMENT OF EPILEPSY.

Theodor Kocher (Archiv für Klinische Chirurgie, 1899) read before the twenty-eighth meeting of the German Surgical Society an extremely suggestive paper upon the operative treatment of epilepsy. He stated that the general feeling of the profession at present in regard to the hope of cure held out by operation in cases of epilepsy was distinctly pessimistic.

While in the early period of what might be called the operative fervor statistics seemed to prove that from sixty to seventy per cent of cases were cured, it has been conclusively shown in later times, and particularly by the tabulations of Graf and Braun, that the number of cases which remain well for more than three years ranges between two and four per cent.

The question is naturally suggested as to whether better results would not be reached by an improvement in the method of operating. A decided advance in this direction was dependent on the suggestion of Hughlings Jackson, as to the advisability of excising a portion of the macroscopically unaltered cerebral cortex, that portion being selected for removal which presides over the motor or sensory functions of the portion of the body to which the aura are referred.

Bergmann records three cures out of twenty operations by this method, only two of which have remained well for three years. Kocher records eight cures lasting more than three years.

In analyzing his own cases and 175 others, collected for him by Schär, Kocher finds in the first place that intervention is successful from any form of operation which reaches and removes the cause of epilepsy. Of nineteen cases in which, by trephining, splinters of bone were found pressing on the dura, adhesions were freed, or abscesses were evacuated, there was improvement in nearly seventy per cent. The results were still more striking when the dura was found lacerated, with splinters of bone projecting into the brain. There was apparent cure in over eighty-five per cent of these cases. Similarly good results followed removal of tumors, whilst operations on cysts are less successful, about forty-eight per cent of these cases recovering. It is, however, evident that failure to cure a larger number of these latter cases is due to the cyst forming again.

In addition to these cases of epilepsy in which the cause can be reached and removed, there is another class of cases in which the affection is evidently due to either focal or general cerebral increase in blood-pressure. When cases of this nature are analyzed, it is found that the cures (meaning by this term freedom from return of epileptic attacks up to the time of reporting the case) are fourteen per cent when the dura is not opened, and fifty-eight per cent when the dura is opened. Hence, incision of the dura has a distinct and peculiar effect—indeed, so marked that the query is suggested as to whether the dural opening is not a curative factor in the cases of excision of the cerebral cortex. The possibility of this being the case is strongly suggested by the cases of Schädel and Nancrede, in which cortical excision seemed to be indicated; yet because of failure to find the cortical center by electrical stimulation, or for other reason, the surgeons restrained from this extreme measure. None the less cure resulted.

Moreover, it is a matter of common observation that after removal of true causes the convulsions cease immediately, or very shortly, whilst after excision of apparently healthy cortical foci, the convulsions may remain unaltered or may even increase in violence. Finally, the statistics of cortical excision show that thirty-three per cent are cured immediately after the operation, while in sixty per cent failure is practically absolute. Statistics seem to show that the results are better when permanent palsy follows cortical excision than when crippling is of a temporary nature.

As to the effect of trephining and opening of the dura, this, Kocher holds, is due to the lessening of blood-pressure which results; the dural opening acting as a valve which quickly regulates changes in blood pressure.

In corroboration of this Schär and Beresovsky, who carefully examined the cases of the cured epilepsy, report that these cases all
show what Kocher calls a valve formation—that is, the membrane covering the trephine opening is perfectly soft and freely movable, sinking when blood-pressure is lowered, pushing outward when it is increased; while in cases which were not cured, the opening was entirely, or in great measure, closed either by bone or by scar tissue so dense as to be practically unyielding.

As a further proof of this, it is noteworthy that comparatively slight injuries to the skull are often followed by epilepsy, while this sequel is rare after severe injuries. Thus Kocher notes that in eighteen cases of complicated, depressed, and extensive skull fracture, there followed but one case of epilepsy. These cases have been under observation for over seven years. Beresowsky found, in the majority of these cases, that the defect was closed by soft tissue, allowing equalizing of pressure. This surgeon, as a result of laboratory study, finds that the dura has an important influence in the form of healing which takes place after trephining. When this membrane is unopened, its outer surface forms true bone, which unites with that forming the borders of the skull opening, and thus completely closes the defect. When the dura is wounded or excised, this bony formation does not take place; hence, when it is desired to form this pressure equalizer, the dura should be excised.

Many authors have urged the uselessness of excising scars which have caused epilepsy, rightly holding that the healing of the operative wound is massively attended by further scar formation. It is, however, noteworthy that scars in themselves are not adequate causes for the attacks. The epilepsy is particularly likely to follow such scars as result from severe inflammation, particularly that incident to infection. The aseptic scars, developing with very slight inflammatory phenomena, do not, as a rule, cause epilepsy.

Not only is this the case, but aseptic foreign bodies are not likely to cause these convulsive attacks. Ito conducted many experiments, introducing foreign bodies into the brain substance, and placing them beneath and above its membranes. These operations were conducted with aseptic precautions, and epilepsy did not develop; while Luciani, who operated without taking these precautions, caused epilepsy in nearly all the dogs upon which he operated. The epilepsy produced in guineapigs by repeated blows on the head with a hammer, but not applied with such force as to cause bleeding, was shown by Ito to be incident to very marked increase of intracranial pressure, this rising to from three to five times the normal. The epilepsy ceased, and pressure was relieved by trephining and opening the dura.

These data prove beyond controversy that an etiological factor in the development of epilepsy is increased intracranial pressure. Cysts play an important rôle as causes of traumatic epilepsy. A large proportion of cases of traumatic epilepsy, operated upon by Kocher, showed these cysts, which were either circumscribed and local or were extensive and communicated with the ventricles, forming traumatic porencephalus. It is evident that all causes, aside from trauma, which effect an increase in the fluid contents of the skull, such as inflammation and tumors, must predispose to epilepsy, since thus there results a marked variation from the normal pressure. In the case of cysts, it is noteworthy that not only those placed near the motor centers, but those in the posterior part of the brain or in the frontal lobes, may cause convulsions by a gentle increase of blood-pressure.

It is the consideration of such facts that leads Kocher strongly to urge that surgeons should always bear in mind the effects of local or general pressure in operating for epilepsy; even when adequate causes, such as bone splinters, thick cicatrices, or cysts, are found and are removed, the question of regulating the blood-pressure of regions other than that particularly affected, or of the entire encephalon, should be carefully considered. For the local regulation of pressure the removal of a piece of bone and the section of the dura corresponding to this bone button is adequate. Kocher uses a small trephine, then enlarges the opening with bone forceps. Afterwards he splits the dura by two incisions at right angles to each other and cuts away the four angles thus left.

For the regulation of the general intracranial pressure, Kocher suggests two methods. In the case of cyst, or of fluid accumulation of the ventricles, he employs drainage, which must be continued for one or more years. A fine silver tube is secured in the opening and is protected by a simple dressing; or the same end may, perhaps, be secured by making very large openings in the skull, the portion of the dura corresponding to the bony defect being removed. Extensive bone defects in themselves, however, sometimes cause epilepsy, which is cured by plastic operation. These convulsions are due to
too marked a change in the blood pressure; hence, for lowering of the general pressure Kocher suggests the formation, of repeated multiple valves such as are observed in the skulls of the people of the stone age. The openings may be formed under cocaine anesthesia, using drills to penetrate the bone, and a fine cannula by means of which drainage may be secured.

Kocher holds that increased intracranial pressure is the unknown factor which is commonly called status epilepticus, this condition being necessary to the outbreak of the affection, and being sometimes inherited, sometimes due to exciting causes such as inflammation, tumors, or trauma. This condition may be remedied both by surgical and medical means.

A most important conclusion from this study is to the effect that epilepsy is frequently due not to the opening of the skull from trauma, but to the closure of the same by the surgeon.

Gussenbauer, in commenting on Kocher’s paper, calls attention to the fact that both excision of cicatrices and osteo-plastic operation with replacement of the bone at the time cure epilepsy.

Bergmann notes that there is customarily a hereditary condition of the nervous system, which predisposes to the development of epilepsy, this condition being especially likely to become manifest in the children of alcoholic parents. Thus, cases should only be termed traumatic in which this hereditary tendency is observed.

The tendency towards spasms may be influenced by lessening of pressure, by valve formation (as indicated by Kocher), or by section of the sympathetic, a recent procedure which seems to be attended with a measure of success. Removal of the direct cause of epilepsy is, however, always the most important indication in the surgical treatment of this disease. When this can be found and remedied, the results are extremely good, even when the status epilepticus has been reached; recurrence will, however, occur even after four years, as in the case observed by Bergmann.

As somewhat corroborating Kocher’s theory, Bergmann reports the case of a child suffering from a porencephalic cyst, originating from trauma at birth. There was unilateral spastic palsy. The intelligence was blunted, and there were epileptic seizures. There was a defect in the skull, over which usually the skin was depressed. During the epileptic attacks the skin covering this defect became prominent. Bergmann has closed the greater part of this defect by plastic operation. None the less, the opening still exists, acting no doubt as a valve. The epileptic attacks have ceased, probably because of the drainage continued for several months.

A theory, based on clinical observation, and one which appeals to the common sense, is always helpful to the surgeon who has to decide for or against operation. The theory of Bergmann is likely to produce renewed activity in the field of operative treatment for epilepsy, and, it is to be hoped, better results than have hitherto characterized efforts in this direction.

Reports on Therapeutic Progress

DIPHTHERIA AND INTUBATION.

The Annals of Gynecology and Pediatrics for April, 1899, expresses the belief, editorially, that intubation has been proven by multitudes of cases, reported and unreported, to be far more generally useful than tracheotomy. Fortunately the introduction of antitoxin makes the need of operative interference much less common than a few years ago. Yet there are occasional cases of dyspnea resulting from the obstruction of diphtheritic laryngitis where the attending physician must do something at once or the little patient will die.

Bokai’s experience, that more than twice as many patients can be saved with intubation as with tracheotomy, together with the fact that the former operation causes less shock, is more quickly performed, needs less preparation and fewer assistants, has led him to give it the preference. He merely insists, however, that the patient must have continuous skilled attention while the tube remains in place. This would seriously limit the usefulness of the procedure in private practice were it not for the help of antitoxin. For we believe we may take it for granted that in hospitals everywhere, on this side of the water at least, intubation is preferred.

But if we accept the dictum that skilled attendance must be at hand in every case, the element of time becomes at once of great importance. Hence we note with interest that nearly sixty per cent of Dr. Bokai’s recoveries were extubated within forty-eight hours, since he has been able to supplement the operation by antitoxin.
Of course in the cities, except in the case of the most wealthy, who can afford to pay for all needed skilled attention, such "chookers" are far safer in the hospitals. But cases of this sort do occur in the country and at a distance from the physician. It is then that the country physicians, who constitute a large part of our readers, must use that faculty almost always so well developed in them, common sense. Presupposing that the physician has the needed instruments and experience, he must consider many elements. Is the case so urgent that he dare not rely simply on antitoxin? Can he arrange to be within short calling distance for forty-eight hours? Is there at hand a reliable nurse who will do as directed and not as the child desires? Shall he have the silk attached to the tube? Fortunately in these days the question of operation for euthanasia is rarely raised. Yet even that may occur.

If he decides that under the circumstances tracheotomy is the only operation permissible, there still remains the question as to whether he shall do a preliminary intubation. There can be no doubt that it is easier to open the trachea of an intubated child than that of a child who is choking and laboring for breath, terrified and struggling, the trachea pulled now this way and now that. But the preliminary operation takes time and skill.

The two great objections to intubation are that it may cause greater obstruction by loosening membrane and pushing it down, and that serious difficulties may follow. They must not be forgotten as possibilities, and must be guarded against as indicated so far as possible.

Intubation for non-diphtheritic stenosis will not occur in the practice of most of us. Yet, if it ever does present itself as a solution to the problem before us, we may profitably remember that it has been successful in many cases and is relatively safe and simple.

The papers of Bokai, as to the value of antitoxin, are one more strong testimonial to the great efficiency of that remedy in combating what a few years ago was the most dreadful and most dreaded disease of childhood.

A CONTRIBUTION TO THE STUDY OF ALBUMINURIA AFTER ETHER NARCOSIS.

The Annals of Gynecology and Pediatri for April, 1899, has an article with this heading, in which Popoff tells us of his researches in this line of investigation. In order to study the question a little more closely some researches were undertaken on the urine of 140 patients in the surgical clinic of the University of Geneva. He employed first reagents for all the urine examined, heat and nitric acid, Esbach's picric acid reagent, and when he found albumin before narcosis he controlled its reaction by acetic acid and ferrocyanide of potassium.

He did not use the centrifugal apparatus for the urine in the microscopical examination, as he only examined the deposits that formed at the bottom of the glass, and these were filtered before examination when necessary. The researches were carried out on the urine of 117 males and 23 females, the urine being from children, adults, and old people, varying in age from ten to seventy years. He only selected patients who were examined for any disease of the internal or external genital organs, and also left aside any urine that was purulent or appeared to be. He examined relatively few women in order to avoid the dangers of error from menstruation, leucocytes, etc. The first urine voided after operation was examined.

Of the 140 examinations, fourteen did not urinate before anesthesia; fourteen presented albumin afterwards where there was none before the administration of ether, and in 112 it was absent both before and after etherization. The fourteen cases of albuminuria before narcosis suffered from varicose ulcers, three from cold abscesses, two from fractures of the hip, one from necrosis, and three from lipoma. Of these fourteen patients ten had Bright's disease, viz., the four cases of varicose ulcers, two cases of cold abscess, two fractures of the hip, and three lipoma. The four others presented amyloid degeneration of the kidneys, this being present in the three cases of cold abscess and in the case of necrosis.

In all these cases Popoff measured the quantity of albumin ten days after the operation, and in one twenty-four days afterwards—that is to say, at the time when the patient left the hospital.

In the fourteen cases where albumin was entirely absent before operation and where it was found in traces after it, it completely disappeared in eight cases the day following the operation, and in the six other cases where it was in such minute quantity that it could not be established the first day after the operation or on the day itself, it had disappeared by the third day. In two other cases the
presence of albumin taken the first day after the operation was fifty centigrammes to the liter, and the second day it could no longer be established; the third day there were still traces, and on the fourth day it had completely disappeared. In another case it was present in traces and had entirely disappeared on the sixth day following the operation. Albumin was constantly present in ten per cent of the cases. Microscopically were found, first, epithelial cells coming from the urethra, bladder, and vagina; secondly, leucocytes, which were more numerous after the etherization. It is difficult to say whether they came from the urethra, bladder, or kidney. Wunderlich, however, believed that they came from the urethra. Thirdly, red blood-corpuscles were found in four cases after narcosis, and in three of six cases were found hemorrhagic casts; fourthly, biliary pigment in only one case; fifthly, indican once; sixthly, crystals of oxalate of lime, uric acid, and urates; seventhly, hyaline, epithelial, granular, and hemorrhagic casts. He never was able to detect the presence of sugar after etherization.

After this study the following conclusions are formulated: First, in the subjects examined in this study, whether afflicted with Bright's disease or not, he never was able to notice any harm done to the general health after narcosis with ether; secondly, a persistent albuminuria will often be increased by the use of ether; thirdly, an ether narcosis may produce an albuminuria, but it is always transient; fourthly, ether may produce casts; fifthly, if casts are present before ether is given, they are increased in number after etherization.

According to Dr. Popoff's personal researches and Wunderlich's work, he says he cannot admit that the albuminuria produced by ether is due to a nephritis, and he believes that it is caused by the physiological action of ether on the blood-pressure.

Now how do ether and chloroform act on the heart? Lenz, Brunner, and Gall remarked that there was a diminution in the blood-pressure when chloroform was given. The blood-pressure increases in the large arteries at the beginning of anesthesia, and often later on becomes lowered. Scheinson also found that there was a decrease of blood-pressure in his experiments on animals, but he did not note any elevation at the beginning of the administration of the anesthetic. This decrease of pressure may be produced by a diminution of the tonus of the arteries, either from a paralysis of the vasomotor system, or from a decrease in the cardiac impulse, or both these causes may be united. Scheinson found the same phenomena in rabbits' ears during the administration of chloroform that Claude Bernard found after section of the sympathetic in the neck—that is to say, a dilatation of the vessel on account of the action of the vasomotors of the bulb. He noticed that chloroform acted directly on the cardiac muscle by diminishing its activity, and that it diminishes arterial pressure and slows the circulation of blood as well.

Now how does ether act? Gall performed comparative experiments on the action of chloroform and ether as regards the blood-pressure; he showed that the decrease is less marked and less-rapid with ether—127 millimeters of mercury with ether and 36 millimeters of mercury with chloroform. The English commission on chloroform which acted in 1863 proved the same thing. At the beginning there was an increase in the heart's action which was longer and more durable with ether than with chloroform, and then there was a depression which was less marked with ether than with chloroform.

Schiff believes that the decrease of blood-pressure produced by ether is due to a paralysis of the peripheral nerves of the blood-vessels. Knoll found in many experiments that ether diminished the cardiac force by a lessened tension in the vessels, and many others have come to the same conclusion.

ICE OR HEAT AS A LOCAL APPLICATION?

Ewart, of London, in The Lancet of April 8, 1899, after a somewhat exhaustive paper on this subject sums up his views as follows: The value of cold as a means of subduing pain and checking inflammation has long been known, but its popularity as a therapeutic agent seems to have fluctuated. Among its most strenuous advocates within modern times have been James Arnott and Professor Esmarch. A summary of Arnott's views will be found in his "Contributions to Practical Medicine and Surgery" (London, 1864). Professor Esmarch's work on "The Use of Cold in Surgery" should be consulted by those interested in the subject. The greater part of his treatise is devoted to the surgical aspects of the treatment by cold, in which he expresses strong belief. He gives illustrations of various shapes of the ice-bag for the limbs, etc., but he had also found good re-
sults from its application to acute rheumatic joints and to the pericardium, and he gives the notes of three cases of acute rheumatism treated in that way. Arnott was not content with ice, but he produced congelation of the surface by a freezing mixture of two parts of ice and one of salt, and found this application, the duration of which was rarely more and sometimes less than five minutes, to be an unfailing means of arresting the pain of sciatica, of neuralgia, and of lumbago. He does not appear to have treated cases of rheumatoid arthritis, but he had tried it in chronic rheumatism with rather less striking results: "An anesthetic temperature will not always be so speedily curative as in the instances of lumbago which have been related."

In lumbago he seems to have obtained immediate and permanent improvement analogous to that which he had noticed in the neuralgic cases. The complications which must have occasionally resulted from the local congelation sufficiently explain the neglect which has overtaken the method. Ice-massage is a much milder proceeding, free from danger, and it would seem equally efficacious. It is interesting to note that Arnott's method has recently been revived for the cure of some laryngeal affections. Abrams reports in the Therapeutic Gazette the immediate cure of functional aphony by freezing the skin with the methyl chloride spray over the spot where the superior laryngeal nerve sends its internal branch into the larynx. In some cases he has had to repeat the process. In other neuroses of the larynx, such as laryngismus stridulus, spastic aphony, and the laryngeal crises of tabes, he has found it of value. He also refers to its efficacy in neuralgia and in peripheral neuritis, and to the linear applications of extreme cold practiced in France under the name of "stypage" for the relief of neuralgia.

Dr. Ewart has had experience of the value of ice-massage as a means of relieving the severe pleuritic pain which commonly accompanies acute pneumonia of the base. The results were encouraging. In the two patients treated the relief of the pain was immediate and the application was welcomed as a comfort. The relief in one of the cases lasted for several hours, but it was not permanent. This suggests that the frequency of applications might be arranged to suit each case.

Although dealing with the local effects of cold this communication would not be complete without a reference to another mode of application successfully employed by Dr. Beverly Oliver Kinnear, of New York. Dr. Kinnear has recorded remarkable results from the systematic use of the spinal ice-bag in chronic rheumatism, and in lumbago both chronic and acute, and he has found the same method of great benefit in various other affections.

The Abdominal Bandage in the Treatment of Enteroptosis.

A. K. Stone, in the Boston Medical and Surgical Journal of May 11, 1899, reminds us that at the conclusion of a paper entitled "Enteroptosis as a Clinical Factor in the Diseases of Women," read in the spring of 1897, he stated that he had not settled to his own satisfaction what was the simplest and best form of abdominal bandage to use in the treatment of this condition. Although he has given the subject much consideration, he says he does not feel sure that he is much nearer the settlement of the problem than he was then; still he thinks he has made out some of the conditions that must be complied with in order to have any success whatsoever in the use of the bandage.

Looking over the bandages to be found in the market, the first thing that strikes one is that they are all made so as to conform to the soft portion of the abdomen—that is, they have a convex curve on the lower border. The result of this is that the bandage practically takes its real lower bearings over the anterior superior spines and the crests of the ilia. This tight band, crossing about midway between the umbilicus and the pubes in many cases, allows the prolapsed intestine to get down into the lower part of the abdomen, press down upon the pelvic floor, and protrude the lower abdominal wall; or, in other words, instead of relieving the enteroptosis the bandage intensifies it. This takes place whether or not there are perineal straps. And this is why so many cases are unrelieved or made worse, when they are simply ordered to go to the instrument-makers and get an abdominal bandage.

Where there is no great prolapse of the pelvic floor, and where the abdominal walls are specially fat and heavy, such bandages give relief, but not where there is true enteroptosis and prolapse of the pelvic organs. To help this condition, the pressure must be so applied that it will be greatest immediately above the pubes. Therefore the lowest and tightest part of the bandage must pass di-
rectly round the body at the pubes, which will make the bearing to be taken just above the trochanters and below the crests of the ilia, and will bring the buckle in the back at the end of the sacrum or the very beginning of the natal fold. At first glance this seems very low, as if it might interfere with locomotion, but a short time given to observing the corsets exposed for sale in shop windows will show that many of them come fully as low as this and occasion no inconvenience. In fact, Dr. Stone says he has never had patients complain of this low bearing of the bandage. What does cause complaint, and is really very disagreeable, especially in hot weather, is the perineal band, which must be worn in practically all cases, so as to keep the bandage in place.

Glénard, who first called particular attention to the condition of enteroptosis, used for his bandage a broad band of elastic webbing with straps at the back and perineal bands, insisting that the elasticity was very necessary for good results. With this opinion Dr. Stone agrees, but does not think it necessary that the whole bandage should be elastic, but only so much as to allow freedom of motion. He has found that however thoroughly and well explanations may have been given, it will be necessary to see the patient a number of times and see the bandage in working position in order to get an idea of the faults and the changes which are necessary to put the bandage in condition to do satisfactory work. In fact, it is necessary to treat the bandage with as much respect as, for example, the orthopedic surgeon bestows upon any of his pieces of apparatus, in order to obtain satisfactory results in the relief of enteroptosis.

Should it be necessary to get special pressure, as, for instance, beneath a floating kidney, Dr. Stone usually begins by using napkins and towels, until he finds where it is necessary to place the pressure and how much padding is required. When this has been pretty well determined, he has the patient or maker sew a pocket on the inner side of the bandage, with greater capacity at the lower part than at the top; this is then stuffed with upholsterer's curled hair and the upper part closed. Some cases require special devices for the support of peculiar internal conditions, and it often means very careful study of the case to determine just what form of support will give relief, but when once made out and the bandage properly applied the result will be worth the pains taken.

**THE USE OF FORMALDEHYDE GAS AS A DISINFECTANT FOR DWELLINGS, VEHICLES, AND HOUSEHOLD GOODS.**

Park, of New York, makes a report on the subject to the *Medical News* of May 13, 1899. As a result of the investigations undertaken in the Department of Health Laboratories on the use of formaldehyde as a disinfectant, and a consideration of the work of others, he believes correct conclusions may be summarized as follows:

1. **Disinfection of Infected Dwellings.**—Exposed surfaces of walls, carpets, hangings, etc., in rooms may be superficially disinfected by means of formaldehyde gas, all apertures being tightly closed, when employed in the proportion of twelve ounces of formalin or five of paraform to each 1000 cubic feet; the time of exposure to be not less than four hours, and the temperature of the apartment not below 52° F. Under these conditions non-spore-bearing bacteria are entirely or almost entirely destroyed when freely exposed to the action of the gas. Spore-bearing bacteria, such as anthrax bacilli, are not thus generally destroyed. But these latter are of such rare occurrence that in house disinfection they may practically be disregarded, and if present special measures can be taken to destroy them.

The penetrative power of formaldehyde gas at ordinary room temperature, even when used in double the strength necessary for surface disinfection, is extremely limited. Articles, therefore, such as bedding, carpets, upholstery, clothing, and the like, should when possible be subjected to steam, hot air, or formaldehyde disinfection in special chambers constructed for the purpose. If not, they must be thoroughly exposed on all sides. Diphtheria bacilli are fortunately among the most easily destroyed bacteria.

2. **Disinfection of Bedding, Carpets, Upholstery, etc.**—Bedding, carpets, clothing, etc., which would be injured by steam may be disinfected by means of formaldehyde gas in the ordinary steam disinfecting chamber, the latter to be provided with a heating and vacuum apparatus and special apparatus for generating and applying the gas. The gas should be used in the proportion of not less than tenfold the amount used for surface disinfection, the time of exposure to be not less than eight hours, and the temperature of the chamber not below 110° F.

In order to insure complete sterilization of the articles they should be placed so as to
allow of a free circulation of the gas around them—that is, in the case of bedding, clothing, etc., these should either be spread out on perforated wire shelves or loosely suspended in the chamber. The aid of a partial vacuum facilitates the operation. Upholstered furniture and other articles requiring much space should be placed in a large chamber, or better, in a room which can be heated to the required temperature. The most delicate fabrics, furs, leather, and other articles which are injured by steam, hot air at 230° F., or other disinfectants, are unaffected by formaldehyde.

3. Disinfection of Books.—Books may be satisfactorily disinfected by means of formaldehyde gas in the ordinary steam chamber as above described, and under the same conditions of volume of gas, temperature, and time of exposure. The books should be arranged to stand as widely open as possible upon perforated wire shelves set about one or one and one-half feet apart in the chamber. A chamber having a capacity of 200 to 250 cubic feet would thus afford accommodation for about sixty books at a time. Books cannot be satisfactorily disinfected by formaldehyde gas in houses and libraries, or anywhere except in special chambers constructed for the purpose, because the conditions required for their disinfection cannot otherwise be complied with. The bindings, illustrations, and print of books are in no way affected by the action of formaldehyde gas.

4. Disinfection of Carriages, etc.—Carriages, ambulances, cars, etc., can be easily disinfected by having built a small, tight, brick building, in which they can be enclosed and surrounded with formaldehyde gas. Such a building is used for disinfecting ambulances in New York City.

5. Advantages of Formaldehyde Gas over Sulphur Dioxide for the Disinfection of Dwellings.—Formaldehyde gas is superior to sulphur dioxide as a disinfectant for dwellings, first, because it is more effective in its action; secondly, because it is less injurious in its effects on household goods; thirdly, because, when necessary, it can easily be supplied from a generator placed outside of the room and watched by an attendant, thus avoiding, in some cases, danger of fire. Apart from the cost of the apparatus and the greater time involved, formaldehyde gas generated from commercial formalin is not much more expensive than sulphur dioxide, viz., 20 cents to $1 per 1000 cubic feet, against 10 cents with sulphur.

Formaldehyde gas is the best disinfectant at present known for the surface disinfection of infected dwellings. For heavy goods it is far inferior in penetrative power to steam and dry heat at 230° F., but for the disinfection of fine wearing apparel, furs, leather, upholstery, books, and the like, which are injured by great heat, it is, when properly employed, better adapted than any other disinfectant now known.

POISONING DURING CHLOROFORM ANESTHESIA IN THE PRESENCE OF A NAKED FLAME.

Under this title Kenelm Winslow tells us in the Boston Medical and Surgical Journal of May 11, 1899, of a recent experience of his own, which he deems worthy of notice, not on account of its extreme rarity, but rather because a similar incident might befall any practitioner, and because it is probable most well-informed physicians are unaware of the reason for, or possibility of, such an occurrence. Dr. Winslow apologizes for the latter statement by admitting that until the happening of the event herein recorded he would have been included with the ignorant majority.

Dr. Winslow says that some months ago he was called by a fellow practitioner—Dr. C. A. Davenport, of Newton, Mass.—to assist at an obstetrical operation. A nurse, under the direction of Dr. Davenport, administered chloroform to the patient, who was on a bed at one side of a rather small room (12x13x8½ feet) in which were burning three gas flames, two in the center of the room and one more remote from the patient. In a short time all except the patient were conscious of a choking, stinging, irritating sensation in the throat and chest, resulting in incessant coughing and gasping for breath. The coughing and choking became so violent that it was utterly impossible for them to proceed with the attempted forceps delivery. They were, moreover, unable to trace the source of the trouble, and after searching unsuccessfully for evidence of escaping coal or illuminating gas were compelled to open all the windows and doors before continuing the operation. The latter was concluded under ether, not because chloroform was suspected to be the cause of the difficulty, but for the reason that the manipulations necessitated prolonged anesthesia. They soon recovered from the immediate irritation of the respiratory passages and without any ultimate ill-effects.
The patient was naturally not cognizant of the casualty until told of it afterward, nor did she suffer any harm whatsoever.

Not long after, being puzzled by the affair and having it in mind, Dr. Winslow noticed the following lines in the New York Medical Record (Feb. 18, 1899, p. 237), in an article entitled “Notes on Anesthesia,” by Emil Aronson: “It is best not to use chloroform by gaslight; the free chlorine has not only killed the patient, but in a recent case also the attending physician, and made two nurses very sick for some time.”

This immediately suggested the explanation of the unpleasant experience noted above. On talking with a number of medical men, Dr. Winslow failed to meet one who was aware of any danger attending chloroform anesthesia in the presence of a flame, and on looking up the matter in the “Index Medicus,” “Jahresbericht der Pharmacie,” “Index Catalogue of the Surgeon-General’s Office, U. S. A.” and “Sajous’ Annual for 1898,” he found but few references, in addition to a few he has been able to gather elsewhere, and most of which he has consulted in the original before writing this paper. There was no reference to any article in any American periodical, and the only mention of the subject he has seen in one—except the few lines in the Medical Record quoted above—is a brief editorial in the Therapeutic Gazette kindly brought to his attention by the editor, Professor H. A. Hare. The only allusion to the matter found in any text-book is that contained in Hare’s “Practical Therapeutics,” wherein it is stated that “Chloroform vapor in the presence of gas flame undergoes certain changes which result in the development of noxious and irritating fumes, consisting principally of hydrochloric acid and chlorine, which produce laryngeal and bronchial irritation.” In regard to the chemistry concerned with the decomposition of chloroform by flame, Dr. Winslow finds that the statements of different writers are generally conflicting as to the probable reactions involved.

This may be readily accounted for, since chloroform may be split into various compounds, according to the temperature and other conditions to which its vapor is subjected in coming in contact with a naked flame. When chloroform is passed through a red-hot glass tube the following reaction ensues: \[2\text{CHCl}_3 = C + 2\text{Cl} - \text{Cl} + 2\text{HCl}\].
The carbon is deposited in the tube. But if exposed to the naked flame in the presence of air and products of combustion (H₂O and CO₂), a somewhat different reaction occurs, in fact apparently varying with the fancy of each medical writer. According to the recent edition of Watt’s Dictionary of Chemistry, which we may consider authoritative, chloroform vapor in the presence of flame acts as follows: \[2\text{CHCl}_3 = \text{CHCl}_2, \text{CHCl}_2 + \text{Cl}\]. Then it is probable that CHCl₃, CHCl₂ (acetylene tetrachloride) further breaks up into hydrochloric acid, chlorine, and carbon, thus: \[2\text{CHCl}_3 = 2\text{HCl} + 2\text{Cl} + 2\text{C}, \text{as before.}\]

Finally, Professor Bosshard (vide Stobwasser) has analyzed the products resulting from the passage of chloroform vapor diluted with air through a flame, and finds that they are: oxychloride of carbon (COCl₂), chlorine, and hydrochloric acid. This result shows that some of the chloroform vapor is oxidized—\[2\text{CHCl}_3 + \text{O}_2 = 2\text{COCl}_2 + 2\text{HCl}\].

Dr. Winslow believes chlorine gas to be the chief resultant and toxic principle responsible for the bad effects observed in chloroform anesthesia in proximity to gas, oil, or other flame, because it is most readily formed and because its characteristic odor and the clinical symptoms bear out this assumption. He has performed successfully the following simple experiment which Professor E. S. Wood was good enough to suggest to him, exhibiting the presence of free chlorine and hydrochloric acid when chloroform vapor comes in contact with gas flame: If a piece of filter-paper be moistened with a solution of potassium iodide and starch and held above a flame—which is allowed to play over an open vessel containing chloroform—the paper is immediately colored blue, because the liberated chlorine combines with potassium and sets free iodine to form blue starch iodide. Again, a strip of blue litmus-paper held above the flame will instantly turn red, through generation of hydrochloric acid, but soon becomes decolorized by the chlorine, which also renders the air irrespirable.

To turn now to the clinical side of the question, the experience of Professor Zweifel furnishes the most extended and instructive, not to say startling, evidence of the dangers attending the use of chloroform near gas flames. No series of prearranged experiments could possibly be more complete, although their author certainly does not appear to have conducted his operations with experimental intent. A number of abdominal sections were performed in an apparently ill-ventilated room under chloroform, and in the presence of three gas flames, one an Argand
burner. In seven cases out of nine catarrhal pneumonia developed, and one resulted fatally. Two of the non-affected patients were operated on during bright days, and so artificial light was not required.

Following the recited incidents Zweifel employed ether on eight patients in the space of as many days, subject to the same conditions and with the assistance of the same artificial light as before, yet with no untoward results. The symptoms of Zweifel's patients were, briefly, tremendous coughing, dyspnea, pain in the wounds, occasioned by the violent muscular contractions, and, in one instance, emphysema of the skin over the chest, caused presumably by rupture of alveoli in the pulmonary interlobar connective tissue and entrance of air, which found its way to the root of the lung, into the mediastinum, thence to the fossa jugularis, and finally to the subcutaneous tissue over the chest.

Dr. Mey, of the Catholic Hospital in Herne, Westphalia, reports an operation for gunshot wound of the abdomen, lasting four hours, under the influence of chloroform and in the presence of gaslight, during which the surgeons and sisters in attendance were overcome by the decomposition products of the anesthetic, one sister dying on the second day following the operation.

Another instance occurred during an operation for strangulated hernia, in which three ounces of chloroform was used, and one-half ounce was spilled accidentally on the floor in a small, badly-ventilated room, heated by an oil stove and lighted by an oil lamp and candle. The anesthetist succumbed first, and all were seriously but not fatally affected with coughing and pain in the chest, lasting for several days in the case of the operator and nurse. The patient is not reported as having suffered at all. The general symptoms in most of the reported cases are constant, dry, spasmodic, and paroxysmal cough, which may affect the patient as well as the bystanders. In one instance it became difficult to prevent the patient from falling off the table, so violent was the coughing. There is a stinging sensation in the nostrils, a perception of a pungent odor, and a feeling of distress and oppression in the chest. Often the patient has stridulous breathing, and heart and respiratory failure are reported. Retching and vomiting occasionally occur.

To further convince us of the danger of chloroform anesthesia in proximity to flame, we have the experiments of Stobwasser conducted on rabbits and guinea-pigs exposed to air laden with varying amounts of chloroform decomposition products. The animals were killed, and their bodies exhibited evidences of bronchopneumonia and edema of the lungs. The trachea was deeply injected, and both trachea and bronchial tubes were filled with frothy mucus. There was also passive congestion of the liver and kidneys, and the blood was dark and coagulated.

**THE HEMORRHAGES OF THE EARLY MONTHS OF PREGNANCY.**

Jardine in an article with this title in the *Scottish Medical and Surgical Journal* for May, 1899, tells us that in his opinion treatment of hemorrhage in the early months of pregnancy differs according to whether it is threatened or inevitable. In the former the patient must be kept quiet in bed. If the bowels are loaded they should be cleared out with a gentle laxative, or better, by means of an enema of soap and water. A drastic purgative must be avoided. The food must be light and non-stimulating. The medicinal treatment aims at quieting uterine action. Opium in one form or other Dr. Jardine thinks is the best drug. The extract of viburnum prunifolium is highly spoken of as a uterine sedative. Dr. Jardine has used it with good results. Hydrastis canadensis is also said to be useful, but he has had no experience with it. Small doses of ergot are also highly recommended by some, but condemned by others. His experience of ergot is that it is very uncertain in its action. This is probably due to the fact that the preparations used are often not freshly made. On the whole, he is inclined to think opium is the best drug to use.

The patient must be kept quiet in bed for a week or ten days. If there is any displacement of the uterus it should be rectified and kept in position by a pessary. We must warn the patient to be specially careful when her next period or two are due. She should rest then. If we find there is a syphilitic taint, we should put her on mercury and iodide of potassium and keep her on it until full term. In cases where abortions not due to syphilis have been frequent, Dr. Jardine has obtained very good results from chlorate of potassium, ten grains thrice daily, all through the pregnancy. [With this latter plan we entirely disagree.—Ed.]

In spite of treatment some cases, which appear to be only threatened, will become inevitable. The line of treatment must then
be changed. In an inevitable abortion we must try to get the uterus emptied as soon as possible. There are several methods adopted. It is a very common practice to give ergot in full doses in the hope that the uterus will completely empty itself. This is a very uncertain method, and Dr. Jardine says he does not recommend it.

In a case where the os is dilated sufficiently we should remove the uterine contents with our fingers. We may be able to express it bimanually. Ovum forceps may be used, but the finger is the best instrument. If we cannot get it all away we must use the flushing curette, and douche out the uterus with an antiseptic. The hemorrhage usually ceases on douching, but in rare cases it continues. The uterine cavity should then be plugged with an antiseptic or aseptic plug. Iodoform gauze makes the best antiseptic plug. The plug should be removed within twelve hours. After clearing out the uterus, ergot should be given for a day or two.

In a case where the discharge is free and the os is not sufficiently dilated to admit of clearing out the uterus, the best plan is to thoroughly plug the vagina after douching it out. Iodoform gauze makes the best plug, but aseptic lint or a kite-tailed plug of pledgets of aseptic wool answers the purpose equally well. Full doses of ergot may be given. The plug should be removed within twelve hours. The ovum will often be found lying on the top of the plug on its removal. If the os is not sufficiently dilated to clear cut the uterus with the finger or curette, we may plug again.

In some cases it may be desirable to clear the uterus at once. Dilatation can be effected by means of dilators, such as Hegar's—the metal ones are the best. Tents are advised, but it is very difficult to make sure that tents are aseptic, and if not, the risk is very great. For that reason Dr. Jardine does not recommend the use of tents.

Very often ergot is given in cases of incomplete abortion in the hope that the retained portion will be expelled, but this is bad treatment. The uterus should be thoroughly curetted with a dull flushing curette. It may be necessary to dilate the cervix to do this. With the patient under chloroform this can easily be done with Hegar's or some other form of dilator. Tents are dangerous. As a rule the bleeding ceases on douching, but Dr. Jardine says he has seen one case in which it did not. The case was that of a young unmarried girl admitted last summer.

She was bleeding freely on account of an incomplete abortion. She was an intelligent girl, but they could not get a straightforward history from her. Dr. Jardine strongly suspected it was a procured abortion. Under chloroform he dilated the cervix with Hegar's dilators, and thoroughly curetted the uterus with a flushing curette. In spite of a douche at 120° the bleeding remained profuse. It was checked completely by an intrauterine plug of iodoform gauze. She made an excellent recovery.

Jardine thinks that in missed abortion, if the os is dilated sufficiently, we should clear out the uterus with the finger or a curette. In a case where there is no attempt on the part of nature to expel it, we should dilate with Hegar's dilators, and separate the mass with the finger and remove it. The cavity should be thoroughly cleared with the flushing curette. Ergot and iron should be given, and we will probably have to treat the endometritis for some time.

In all cases where any examination or operative interference is necessary, the strictest antiseptic and aseptic precautions must be taken. The after-treatment in all is the same as after a full-term labor. Douching as a routine is not necessary unless there is sepsis, and then it must be done carefully and thoroughly. The patient should be kept in bed for at least a week. We will find this is a difficult task, but we should insist on it. Ergot is usually given to hasten involution.

If the abortion is a complete one, the usual after-treatment is all that is required.

Dr. Jardine leaves the consideration of prophylactic treatment to the end because, as a rule, we are not called upon to use it until the woman has had at least one abortion. The best prophylactic treatment in many cases is to properly treat abortions so that the uterus will return to a healthy condition—i.e., to thoroughly clear it out and keep the patient quiet until involution has occurred. She should not resume intercourse until involution is complete and the endometrium is in a healthy condition. If syphilis is present, she should be put on antisyphilitic remedies. The husband should also be treated, but Dr. Jardine says he must warn us to be extremely careful in dealing with cases of this kind, as we may very easily upset the peace of a home.

In cases of endometritis, intercourse should be prohibited until the condition is cured.
Jardine has seen many cases of abortion in patients who became pregnant before their endometritis was completely cured. If there is anemia or other constitutional weakness present, suitable treatment must be adopted. In cases of habitual abortion from degeneration of the placenta, chlorate of potassium is a most useful drug. [We disagree with this.—Ed.] We should give it continuously during pregnancy. If the uterus is displaced we must replace it and put in a pessary to support it. We should always warn our patients against overexertion, especially at times corresponding with the menstrual periods, and more especially at the time corresponding with former abortions.

ON THE USE OF ANTISTREPTOCOCCIC SERUM IN INFECTIONS BY THE STREPTOCOCCUS.

In the *Medical News* of May 6, 1899, Browne tells of his use of this serum in the treatment of a number of cases. He used the serum made in the biological laboratories of Park Davis & Company.

It is well known to bacteriologists that the protective power of antistreptococcic serum is low at present and varies considerably, some specimens being fourteen times the potency of others, according to Marmorek's own statement. It seems idle, therefore, to expect results from a timid use of a relatively feeble serum. If good is to be expected from the use of the serum in this class of cases, it must be used in far larger doses than hitherto. Quantities of less than sixty cubic centimeters a day will not as a rule avail much, and much greater daily quantities may be necessary. Moreover, it must be used early in the disease, before multiple abscesses have formed in the uterine walls and septic thrombi have collected in the vessels of the pelvic structures. It has been noted in commenting on the use of this serum in the phlegmonous cases that while it seemed to limit the range of infection, or prevent suppuration where this had not already occurred, after pus had actually formed drainage was still absolutely essential to the recovery of the patient. The same rule will evidently apply to the uterine cases. This is probably the chief reason why the results of the serum in the puerperal cases have been so discouraging. The serum has been used late, after septic foci have been established and drainage has become a necessity. This, however, is most difficult to secure without the shock of a hysterectomy, in itself sometimes sufficient to carry off the patient. The early and free use of the serum will, it is to be hoped, give better results.

What is the proper dose of the serum? This is a practical question, and at present it can only be answered by saying that too much rather than too little must be given, because the serum has not as yet been standardized. An average dose is ten cubic centimeters. Twenty cubic centimeters will often be required, and daily quantities of 60 to 100 cubic centimeters may be needed. It is possible that the varying experiences of different observers have been due to the use of serums of different degrees of strength. It is not possible to give a definite dosage until the manufacturers succeed in standardizing their products, something which they hope to do at no far distant date. Until this has been accomplished the experiences of different observers must be of quite limited value.

In connection with the question of dosage, a second most practical query will suggest itself as to the possible dangers incurred in introducing large quantities of foreign serum into the circulation. Aside from the occasional appearance of erythema and urticaria, Dr. Bristow does not believe that any serious risks are to be apprehended. In a series of reports of more than 1000 cases collected by him, the only instances in which the serum was charged with ill effects were in four or five puerperal cases. The unfavorable symptoms were classified as follows: sudden high temperature; collapse; uncontrollable vomiting. If these symptoms were the result of the serum we should expect to hear of their occurrence in some of the 800 remaining cases of the 1000. On the contrary, there is no record of such symptoms except in the puerperal cases, notwithstanding that much larger doses were given to children particularly, one child receiving 263 cubic centimeters and another 90 cubic centimeters. Now it is a fact that these very symptoms (sudden high temperature, obstinate vomiting, collapse) are all features in the pathologic history of abdominal sepsis. It does not, therefore, seem good reasoning to attribute these symptoms, evidently coincidences, to the use of the serum when it cannot be shown from the evidence at hand that they occurred in any other of the 1000 patients, but as a matter of fact occurred in those instances alone in which they were to have been expected apart from the use of the serum.
The serum has been used in cases of so-called malignant endocarditis with success, and in the bronchopneumonia of children (forty-five cases, Marmorek) without a single death. This affection, Marmorek states, is almost always of streptococcic origin. Considering the usual mortality of the disease in children this record is noteworthy.

ACUTE INFLAMMATION OF THE TYPANIC CAVITY.

S. McCuen Smith, in the Philadelphia Medical Journal of May 6, 1899, expresses the belief that the treatment of acute inflammation of the tympanic cavity will largely depend on the cause, stage, and severity of the attack. If the origin is catarrhal, and treatment is instituted during the stage of hyperemia, the inflammation will be arrested and confined to the seromucous or non-suppurative stage. If, however, this early care has not been given, the case will likely progress to the stage of suppuration, and rupture of the membrana tympani. The presence of deep-seated pain, increased by pressure over the tragus, calls for immediate bloodletting in front of the tragus. For this purpose Dr. Smith strongly urges the use of the artificial leech, on account of its convenience and efficiency; one or two cylinders of blood (or its equivalent, three or four Swedish leeches) should be extracted.

If bloodletting cannot be resorted to in young children, a blister will answer a fairly good purpose. The application of either dry or moist heat will give much relief in incipient cases; the first can be applied either by the hot-water bag, or by the bag of hot salt; the latter by instillations of a hot saturated solution of boric acid, the ear to be protected by a piece of cotton placed in the external canal, and worn for some time after the pain has subsided. The nasopharynx should be carefully examined and treatment applied to correct any abnormal condition.

Small doses of calomel and soda should be administered, until free purgation is established. A coryza tablet, composed of atropine sulphate \( \frac{1}{15} \) grain, arsenous acid and strychnine sulphate of each \( \frac{1}{15} \) grain, mor- phine sulphate \( \frac{1}{15} \) grain, quinine sulphate \( \frac{1}{15} \) grain, and camphor \( \frac{1}{4} \) grain, should be taken every hour until a decided dryness of the throat is produced; then continue every two or three hours, for two or three days. Salol and phenacetine, or antipyrin, will be of service in appropriate cases, especially if there is a rheumatic tendency, or if the pain is severe.

It is assumed that if the patient is seen before suppuration has occurred, every effort will be made to arrest or modify the disease without surgical intervention. If, however, the disease does not yield to the treatment outlined, and the pain continues, with or without bulging of the membrana tympani, the membrane should be immediately incised, the point of election usually being the posterior inferior quadrant. As it is possible for the pus to be confined either to the superior or inferior portions of the tympanic cavity, it is best to incise the membrana tympani at the most dependent point, always bearing in mind that the object to be accomplished is the free evacuation of fluid from the middle-ear cavity. The drumhead should never be punctured, but, on the contrary, a free incision should be made, always extending it down to the inferior surface of the canal, so as to insure good drainage; otherwise the suffering and danger incident to the confined pus will continue. Care should be taken that the incision shall not interfere with the ossicles, and that it shall be done under proper antisepctic precautions.

Syringing of the ear should not be employed in acute suppurative otitis media, unless there is some special indication for its use. The discharge should be removed by cotton twisted on an applicator, some hydrogen peroxide instilled, and allowed to remain in the canal for four or five minutes; then dry the canal with cotton, introduce a small strip of iodoform gauze, and place a small plug of absorbent cotton exterior to the gauze, to catch the discharge. This dressing should be renewed daily for a week, when the case should begin to improve, and thenceforward will require less frequent dressing.

After the acute symptoms have subsided, it is well to rid the tube and middle ear of any retained pus by Politzer’s method of infil- tration, to be repeated about once a week if found necessary.

THE OPIUM HABIT IN CHILDREN.

The Archives of Pediatrics some time since referred in its pages to the disastrous results which follow the improper administration of opium in pediatric practice. No other drug in the materia medica requires more intelligence and discrimination in its use. This being true in the hands of skilled physicians, it is self-evident that it cannot be used by
the laity with impunity. Many deaths are unquestionably caused by it every year, while the number of babies who are forced into the opium habit is appallingly large. At the Babies' Hospital in New York careful investigation recently showed that over half of the patients received under six months of age had been systematically drugged with opium in the form of paregoric or soothing syrup. Attention is again called to the subject by a discussion in the May number.

An infant may become as firmly addicted to opium as an adult, and feels as keenly its withdrawal. Sudden stopping of the drug is marked by restlessness, wakefulness, and every indication of suffering and distress. An infant has been seen, to whom paregoric had long been given regularly by a nurse, in a state bordering upon a frenzy twelve hours after the nurse's enforced absence.

Infants acquire the opium habit in one of three ways: through the mother, who does not realize the harm she is doing, but resorts to soothing syrup or some other opium preparation to obtain quiet and rest for herself; through the nursery maid or other attendant, who neither knows nor cares what the result may be so long as she is spared from trouble; through the monthly nurse, many of whom make capital upon their ability to keep a child quiet.

In the first of these cases the doctor is often at fault in advising the administration of paregoric for the minor aches and pains of the infant. For the relief of pain no drug equals opium. When actual pain is present, it may be given to children with perfect propriety. Condemnation cannot be too strong, however, against its use for the lesser ills and aches. It should never be used for sleeplessness, unless due to actual pain. It is so prompt and effective in its action that the mother is tempted to resort to it again and again. It is unwise to allow a mother to suppose that she can use paregoric. If it is indicated, let it be prescribed or left diluted ready for use. A few tablets may be carried, each representing ten minims of paregoric. These can be left with the assurance that no more will be given than is intended, and the mother will be in ignorance as to their exact nature. When a child is cross and irritable, the temptation to the mother to repeat an opiate is very great, and should be guarded against as far as possible.

Among children's nurses the habit of resorting to opiates is unfortunately very common and wide-spread, and accounts for many obscure and unexplained symptoms among their charges. A nurse who boasts much of her ability to keep an infant quiet, be she a nursery maid or a monthly nurse, should be an object of suspicion. It is rare that positive proof can be obtained, but the circumstantial evidence is frequently very strong. The presumption is strong when an obstetric nurse habitually has docile and abnormally quiet infants who become restless and wakeful a day or two after she leaves the house. The mother usually blames herself, and attributes it to lack of knowledge and experience on her own part. She is prone to have profound respect for the superior ability of the nurse. Too often the true explanation of the baby's change is an entirely different one.

While it would be a great injustice for the physician to be suspicious of every nurse, and cruel to charge such practices without ample warrant, he should, nevertheless, have ever in mind such possibilities. He should not be blind to the fact that the opium habit is not uncommon among little children, and he should never be the means of establishing it by injudicious advice to mothers and nurses.—Archives of Pediatrics, May, 1899.

SHOULD THE UNITED STATES PHARMACOPEIA RECOGNIZE VERATRUM ALBUM AND VERATRUM VIRIDE AS ONE DRUG?

H. C. Wood and H. C. Wood, Jr., attempt to answer this question in the American Journal of the Medical Sciences for May, 1899. As the result of their whole series of experiments, they conclude that the only evidence which they have been able to obtain of differences in the action of Veratrum viride and Veratrum album is that Veratrum album more frequently purges man when taken in toxic doses than does Veratrum viride, and that some specimens of Veratrum album are stronger than are some specimens of Veratrum viride. On the other hand, it would seem, however, probable or even assured by the experiments that different specimens of Veratrum viride may vary greatly in their strength, and that some specimens of Veratrum viride may be stronger than some specimens of Veratrum album. It is not probable that a clinician would be able to perceive any difference in the action of the therapeutic dose of the two plants, so that it would be proper for the Pharmacopoeia to recognize both species, if any advantage could be gained by so doing. A national
pharmacopœia should, however, according to Dr. Wood's idea, favor the use of American drugs when it can do so without injury to any one. The recognition of *Veratrum album* would be an aid in the substitution of an American by a foreign drug which now has very little vogue in our markets, and which possesses no advantages whatever over its American representatives. Any difference which may possibly exist between the two Veratrums is in favor of the American drug as less apt to disturb intestinal digestion. Under such circumstances the recognition by the United States Pharmacopœia of the European drug seems to them of doubtful expediency.

**INSANITY IN CONNECTION WITH DISEASE OF THE DUCTLESS GLANDS.**

The *Medical Record* of April 29, 1899, contains an article by Hamilton on this subject. In its course he remarks that the results of the administration of organic extracts for the treatment of mental diseases of the kind described, and, in fact, of many psychoses with no such origin, have been, to say the least, interesting, especially when the thyroid has been administered either in the raw form or in powder. Babcock has had particularly happy results in cases having diverse characteristics, and his experience has been shared by many others. In his list of patients, which included examples of stuporous, melancholic, cerebral exhaustion, and chronic disturbed cases, there was a prompt clearing up and elevation in temperature, and in some cases an increase of hemoglobin of at least twenty per cent. Occasionally there was more marked mental depression, which was followed by a stimulation of intelligence. Osler reports a series of cases in which the most wonderful transformation took place in cretinous and myxedematous subjects, and in which a decided amelioration of the mental as well as the physical symptoms took place when large doses of the powdered thyroid were given.

Dr. Hamilton says his experience, while less extensive than that of others, has led him to believe that at least in chronic depressed states this organic extract sometimes does much good, and especially encouraging results were obtained in a case of chronic insanity with erotic delusions, seen in consultation with Dr. Dana. So fixed had been the patient's mental disease, and so many plans of treatment had been tried unsuccessfully, that it was with slight hope that they prescribed the powdered thyroid; but the prompt subsidence of the symptoms, the greater or less improvement of general intelligence, and even the disappearance of physical indications of dementia, fully justified the experiments. The patient during the administration of the powder improved, but after a time relapsed into her old stuporous condition, when it was discontinued.

The duration of the beneficial results attending the use of thyroid extract does not appear to be so lasting in ordinary insanity as it does in the true thyroidal insanities, possibly because the cerebral malnutrition and cortical changes are too deep-seated. In the insanity of acromegaly Andriezen has used powdered pituitary gland with benefit.

In stuporous melancholia and psychoses in which the katatonia symptom-complex was present, it has been of use. Splenic glycercine has been recommended and used by Clark, of Scotland, who noted as much as fifteen per cent increase in the pulse-rate, with slight temperature elevation in depressed cases, and with slight increase of weight and an improvement of the condition of the skin, together with a lightening up of the stupidity of the patient. This observer also noted that in all cases of insanity the weight of the spleen was below normal.

The interesting physiological results of Schäfer, who experimented with the adrenal extract, and demonstrated that when it was injected into the veins there was a decided if not lasting effect upon the arterioles, which were contracted as the result of its use, and if taken by the mouth a general diminution of the caliber of the arteries could be detected by Oliver's arteriometer, has led Dr. Hamilton to try it in mental cases. While it has been used as a substitute for cocaine as an application to the mucous membrane, as recommended by others for surgical operations, it has not yet been administered internally, although Gilman Thompson has suggested its employment in hematemesis. Dr. Hamilton has used it in cases of exophthalmic goitre with decided benefit, and in two cases of hysterical mania it promptly reduced the excitement and produced sleep when divided doses of from five to twenty grains were taken. Its effects, while not lasting, are certainly preferable to those of some narcotics, and it is possible that it may sometimes be indicated as a substitute for morphine or hyoscine. When morbid mental states are the result of toxemia it may be administered.

Just how important are the relations of the
internal secretions to each other, and how much their variations are likely to be followed by the development of psychic symptoms if not by actual physical change, is so far indeterminate, and can be tested only by experiment. It would appear that in the hands of Ringer, Phear, Lloyd-Jones, Dyson, Park, and others, adrenal extract has done little good in Addison's disease, although a slight improvement in the mental dulness and weakened condition of the circulation followed. In a case reported by Dyson, of a girl of thirteen years, in whom a progressive loss of memory and maniacal excitement and coma preceded death, the tincture of the adrenal gland was given without effect. It does not appear that thyroid extract was tried.

**OOPHORECTOMY AND THYROID TREATMENT IN CANCER.**

The effects of the menopause on the generative apparatus, and on the breasts in particular, suggested to certain enterprising surgeons some time since that malignant growths of the breast might be favorably influenced by an artificially induced menopause, as, for instance, by ablation of the ovaries. On the whole the results of the operation, though not devoid of interest, have not proved quite as successful as had been hoped. Subsequent observations by a method in which the administration of thyroid extract was associated with the removal of the ovaries have given much more promising results, though one is quite at a loss to explain the modus operandi of the combined treatment or to apportion the relative merits of the two factors.

At a recent meeting of the Medical Society of London, as reported in the last issue of the Medical Press and Circular, Dr. G. Herman recorded a second case in which this operation, plus the administration of thyroid gland, had given results so successful as to be remarkable. In this particular case the treatment had brought about the healing of a large carcinomatous ulcer of the right breast which had recurred after two operations for removal by surgical means, and had determined the disappearance of a large tumor in the other breast, the nature whereof was sufficiently indicated by the enlargement of the corresponding axillary glands, which glands also had ceased to be perceptible to the touch. These results are sufficiently remarkable to merit attention, especially in view of the unsatisfactory results of purely surgical measures, which are at best but palliative. Mr. Stanley Boyd inclines to the view that the improvement is really due to the oophorectomy, but statistics hardly bear out his contention, for Dr. Herman had no trouble in showing that the results after oophorectomy alone were not nearly as good as when the thyroid treatment is superadded. Further experience will show which of the two factors plays the most important rôle in producing these results. It seems, however, that oophorectomy, if it is to be of service, must be done before the cessation of menstruation, for in several recorded instances no effect has followed their removal after the menopause. This is what one might have anticipated, though from another point of view it seems odd that if the artificially induced menopause exerts such a marked effect the natural process should not confer similar quasi-immunity against cancer. This fact tends to support the view that oophorectomy alone is not sufficient to determine a constitutional change capable of inhibiting malignant growths. Dr. Herman suggests that the withdrawal of the ovarian secretion and the presence of an excess of thyroid secretion render the tissues less amenable to the ravages of the hypothetical parasite of cancer, and this explanation is in accordance with the results so far obtained.

Has excessive thyroid secretion any direct influence in conferring immunity against cancer? This question ought not to be difficult to answer, for we have only to ask ourselves whether on the one hand women who suffer from exophthalmic goitre ever develop cancer, and whether, on the other hand, myxedematous patients display any marked predisposition thereto. We must not forget, however, that cancer has its vagaries. There is the well known case of Mr. Gould, in which a patient apparently dying from cancer, and regarded as past treatment, suddenly took a turn for the better, and ultimately made a perfect recovery without treatment of any kind. There are, indeed, plenty of cases on record of the spontaneous subsidence of cancer, and it is hardly in accordance with scientific methods to dismiss all instances as examples of faulty diagnosis. That is merely begging the question at issue. We must not allow our judgment to be warped by preconceived pathological notions. It is possible, and indeed probable, that the microscope alone does not enable us to establish absolutely the malignancy of a tumor. Malignancy, moreover, is essentially a clinical
term; it characterizes growths in which from microscopical data one would not have expected it, while it is sometimes absent in growths which, as far as microscopical evidence goes, are doomed to rapidly fatal development. These facts should teach us not to be too dogmatic, and not to pin our faith to such a kaleidoscopic science as pathology, which, useful when taken in conjunction with clinical observation, is apt to prove misleading when erected into a scientific dogma. We shall probably not have long to wait for further and more extensive observations on the lines which we have sketched, and these will serve to teach us the limits of the treatment and possibly, later on, the precise method of its action.—Medical Press and Circular, April 19, 1899.

SOME OF THE LESS COMMON EFFECTS OF MALARIA, WITH REMARKS UPON THE TREATMENT OF CHRONIC INFECTION.

The Medical Record of April 29, 1899, tells us that Dr. William H. Thomson contributed a paper with this title to the meeting of the New York Academy of Medicine, held April 20, 1899. He said that in 1862 he published a paper in which he argued that the chief facts concerning the communicable diseases could be explained only on the assumption that they were due to microorganisms, but this assertion had been received with much ridicule, as the prevalent belief at that time had been that these diseases were due to volatile poisons. But long after that time malaria held its own as a disease of this class—a distinct miasm, as its name implied. Our point of view in regard to malaria has, however, wholly changed, and our present view regarding it constitutes a very great advance in medicine. If the inoculation theory should become thoroughly established, it would mean practically an effectual check to the spread of malaria. Dr. Thomson said that in 1896 he had had in his hospital services two cases of fatal cerebral malaria, in which the diagnosis had been verified by autopsy. Both patients were Germans over sixty years of age, and both had contracted the disease while working in gardens on Long Island. The temperature had varied between 99° and 101° F. for eighteen days. Although vigorously treated, there had been no diminution in the large number of plasmodia present in the blood. Their condition resembled that of one suffering from uremia. At the autopsy the cerebral vessels had been found loaded with pigment. Such cases should suggest that when the origin of a febrile coma was obscure, the blood should be examined for the malarial organisms.

In those functional nervous affections, such as periodical neuralgias, dependent upon malarial infection, Dr. Thomson had had much success from combining ergot and quinine, even when large doses of quinine, antipyrin, and similar remedies had totally failed previously to give relief. In every case of this kind ergot had been uniformly successful. In some of them the administration of moderate doses of quinine with the ergot had produced cinchonism, which had not been the case when much larger doses of quinine had been given without the ergot.

If every first attack of malaria be treated carefully for six weeks, the author felt sure that there would be few cases of chronic malaria. Numerous observations on the incubation period following the first infection have shown that it varies very greatly in different persons. It was this feature of latency that persuaded patients to drift on without systematic and sufficiently prolonged treatment. The blood should be examined microscopically at intervals for at least nine months after apparent recovery. Chronic malarial infection implies a personal susceptibility, either original or acquired.

The treatment of malaria which Dr. Thomson would recommend begins with a mercurial laxative, given toward the close of the febrile paroxysm. The quinine should be administered from one to two hours before the time for the chill, but as one large dose is apt to disturb the stomach, it is better to give the desired quantity of quinine in three equal doses at intervals of two hours, the last one being given one or two hours before the chill. A most valuable adjuvant to quinine is ginger, given in the same dose as the quinine. Another useful addition is capsicum, in one-fourth of the dose of quinine. It is a curious fact that the first dose of this combination usually acts as a free purgative. In forty-seven cases of Cuban malarial fever that had resisted the usual treatment last fall, the author had adopted the plan of giving camphorated tincture of opium as an adjuvant to the quinine, and with remarkably good results, as already published. Perhaps the most striking action of this combination was in the improvement of the general condition, and the buoying up of the spirits. A
good method, at times, of administering the
paregoric is by mixing it with the old com-

TESTINAL OBSTRUCTION.

The last number of Schmidt's Jahrbücher
contains a review of some interesting contribu-
tions to this important subject. Professor
Heidenhain, in discussing the cases that have
come under observation in the clinic at
Greifswald during the past few years, main-
tains that clinical experience absolutely de-
montstrates that intestinal obstruction may be
in some cases the result of a purely functional
disturbance of intestinal peristalsis. In three
cases a spastically contracted portion of small
intestine was found at operation as the cause
of the acute symptoms. The serious disturb-
ance of peristalsis had been brought about in
one case by a stricture of the rectum high up,
in a second by a volvulus involving the large
intestine at the sigmoid flexure, and in a third
by the presence of a roundworm.

In cases in which any chronic disease of
the intestine exists every possible precaution
should be taken to avoid disturbing the al-
ready irritated peristalsis by anything calcu-
lated to produce additional reflex excitation.
Only the most bland food should be permit-
ted, and every excess strenuously prohibited.
Acute intestinal obstruction from bunches
of roundworms knotted together has been
noted before, but now for the first time
the direct irritation due to the presence of
a single worm has been reported as causing
sufficient spastic interference with peristalsis
to set up acute obstructive symptoms.

Three patients in whom complete intesti-
nal obstruction was diagnosed were re-
lieved by high injections. Under these
circumstances doubt still remains whether
the condition was due to any of the ordinary
serious causes of true obstruction or was
occasioned by an extreme degree of copro-
stasis. Heidenhain think that obstruction
due to ileus at the sigmoid flexure, a not
infrequent condition, may be relieved by
injections—not, however, if the twist of the
gut is more than 270 degrees. Operation
for this condition, followed by fixation of
the intestine, has given excellent results in
Heidenhain's hands.

An interesting commentary on Professor
Heidenhain's success with high injections in
certain cases of acute obstruction is found in
the report of Dr. Barker's experience with
fifteen such cases. In six cases he succeeded
in reducing the intussusception by water or
air injections. The tumor so changed its
color on palpation that no doubt of the
reduction seemed possible. In every case,
however, it recurred; in a few hours it could
be felt as before, and necessitated operative
interference. Of the fifteen patients, ten
recovered. Eleven of the patients were
children under sixteen months of age; one
was an adult, aged thirty-two; the others
were children, aged respectively four, five,
and twelve years.

While injections of air and water still have
a place in the therapeutics of obstruction,
they must evidently not be allowed seriously
to delay surgical procedures, which are al-
ways to be thought of at once. In intussus-
ception in children where it was hoped
injections would be effectual they have
proved of doubtful utility, and may only
make the eventual prognosis worse by delay.
It is clear, however, that as diagnosis be-
comes more exact operations are undertaken
earlier, and the percentage mortality from
acute intestinal obstruction is ceasing to be
the opprobrium to modern surgery that it
formerly was.—Medical News, April 29,
1899.

S A L I N E S O L U T I O N I N S E P T I C E M I A
A F T E R A B O R T I O N.

Ostermayr (Centralblatt f. Gynaekologie,
No. 12, 1899) relates how a very bad case of
septicemia was successfully treated by small
subcutaneous injections continued for a fort-
night. The patient was twenty-six, and it
transpired that her husband had induced
abortion. Ostermayr was called in on No-

November 25, 1898, for metrorrhagia. On the
27th a rigor set in; the curette being used,
much placental and decidual tissue was re-
mo, with old clot. A few days later
jaundice was observed, then toothache, with
periostitis of the adjacent part of the upper
jaw. On December 8 the periosteam was
incised and pus let out. General erythema
and high temperature and pulse were next
observed. By December 14 the patient was
in a desperate condition; 300 grammes of a
0.9-per cent saline infusion was injected into
cellular tissue of the right infraclavicular
fossa. On the 15th she was very ill; another
injection was given. The patient then began
to improve. Vomiting and diarrhoea, which
had been severe, ceased, and the pulse, which
on the 14th was too feeble and rapid to count,
dropped to 108 and was strong. Urine be-
gan to be freely secreted. From the 16th to the 20th two subcutaneous injections of the saline solution were given daily—the last, once daily, were given on the 21st and 22d. The pulse was about 100, the temperature 98° to 100°; the erythema had nearly disappeared. By December 21 the patient was quite well. Ostermayer notes that the first infusion, injected on the evening of the 14th, was not absorbed till the following morning, yet temporary good effects were already observed. After the 18th the infused solution was absorbed within three hours.—British Medical Journal, April 22, 1899.

Salicylate of Methyl.

Among recently introduced drugs salicylate of methyl seems to be one likely to prove of considerable use, and Schoull contributes an article on the indications for its use (Journal de Médecine, March 10, 1899). It is more particularly in the articular manifestations of rheumatism that it is successful, especially as a means of relieving pain, which disappears very rapidly under its administration, much more so than with salicylate of soda. The swelling of the joints is somewhat longer in disappearing, as is also the temperature, and salicylate of soda seems in this instance more efficacious. It is therefore proposed to administer the two salicylates together, under which circumstances the similar dose of the soda salt can be employed. Schoull has also employed a combination of salicylate of methyl and antipyrin, and has thus obtained some surprising results in the reduction both of the pain and temperature. He points out that the amount of urine should be watched during the administration of this drug. Salicylate of methyl is also of extreme advantage in subacute and chronic rheumatism, in which cases it presents a marked superiority over the soda salt. The same may be said of gouty arthritis. In certain other infective conditions, as gonorrhea, syphilis, and erythema nodosum, the effects, though good, are not so striking. The writer quotes Roger as having obtained very good results in the arthritic complications of eruptive fevers, especially scarlet fever, in which the action of antipyrin, salicylate of soda, or salophen is slight. The drug is also efficacious in neuralgia, sciatica, some forms of neuritis, herpes zoster, and lightning pains of tabs. Schoull has also tried salicylate of methyl in cases of orchitis from mumps, and with remarkable results, all the symptoms disappearing in two days. Even in cases of epididymitis the effects are very favorable. The treatment of mumps itself by salicylate of methyl has been tried by Picard, of Troyes, with considerable success.—British Medical Journal, April 22, 1899.

The Indirect Treatment of Hepatic Cirrhosis.

Cardarelli (La Riforma Medica, March 11, 1899) deals chiefly with the treatment by milk diet, of which he speaks highly. In the cases in which it does good, the urine increases in quantity, the urea increases, and the uro-erythrin disappears. These good effects may not be seen all at once; they may be delayed, especially where there is much abdominal tension. Small quantities (half a liter or even less) should be given at first. If milk cannot be borne, large doses (40 to 50 grammes) of lactose may be given in weak broth. To test the power of absorption, the author recommends an enema containing five to six grammes of salicylate of soda, which may be looked for in the subsequent urine. The most reliable indication for paracentesis abdominis where there is ascites is the quantity and quality of the urine and the presence of edema of the lower extremities. In performing paracentesis, the author prefers the gradual method of extraction by Southey’s tubes.—British Medical Journal, April 22, 1899.

The Use of Holocaine as a Local Anesthetic in Eye, Ear, Nose, and Throat Operations.

In the New York Medical Journal of June 17, 1899, Guttmann concludes an article upon this subject with the following summary of his views. He thinks that in a discussion as to the relative merits of local anesthetics, eucaine, as compared with cocaine and holocaine, may be left entirely out of consideration, inasmuch as it not only has no advantages over these remedies, but has positive disadvantages. As regards holocaine and cocaine, the results of Dr. Guttmann’s investigations on healthy eyes may be briefly summarized as follows: Both cocaine and holocaine possess the common property of paralyzing the terminal filaments of the sensory nerves, and both are therefore good local anesthetics. For practical purposes there is no great difference between them, as regards the time of onset or the duration of anesthesia. Nor do they materially differ
in the intensity of the resulting anesthesia. Either remedy may therefore be used indifferently in the ordinary operations on the eye. But whereas the cocainized eye, in his experience, was pale, protruding, of lowered tension, with the pupil dilated and the fissure of the eyelid enlarged, the holocainized eye was red and inflamed, of normal tension, not protruding, pupil normal, and palpebral fissure not enlarged. This difference in the effects of cocaine and holocaine is explained by the well known action of cocaine as an irritant to the terminal sympathetic nerve fibers, and its consequent vasoconstrictor effects. The pallor of the eyeball is therefore due to the powerful contraction of the blood and lymph vessels following the application of cocaine. The haziness and dryness of the cornea are also due to the vasoconstrictor effect of the cocaine, although the abolition of the reflex nictitating functions of the eyelids, as a result of the anesthetic condition of the eye, is also partially responsible for them. But neither in Dr. Guttmann's observations nor in the experiments of others was any effect of holocaine on the sympathetic nerves to be observed.

From these observations we may derive conclusions as to the indications for the use of either one drug or the other. For the removal of a foreign body from the cornea holocaine is to be preferred, for unlike cocaine it does not produce the subsequent disagreeable mydriasis; also for a strabismus operation is holocaine to be preferred, for cocaine causes the muscle to shrink, and thus often permits some muscular fibers to escape the strabismus hook.

In the treatment of inflammatory affections of the conjunctivea and cornea, associated with painful blepharospasm, holocaine is of great value, for it not only relieves the spasm and allays the pain, but also acts as an antiseptic, and thus as a curative agent. But on the other hand, cocaine is to be preferred in the performance of an iridectomy where the arteries appear atheromatous and where we would avoid a considerable hemorrhage. The vasoconstrictor effect of cocaine, and the diminished tension of the eyeball, together with the subsequent deepening of the anterior chamber, are all factors in favor of using cocaine for the performance of an iridectomy under these circumstances. For the extraction of a cataract where the pupil is small, cocaine is to be preferred on account of its mydriatic action. For the many other operations on and about the eye, these two agents may be used indifferently, unless, indeed, the bactericidal action of holocaine should incline us to use it in preference to cocaine. This latter consideration is sometimes of great importance, especially if we consider the time and trouble that is required to sterilize a solution of cocaine.

In choosing our anesthetic for operations on the ear, nose, and throat, we must consider whether the disadvantage of the freer hemorrhage following the use of holocaine is more objectionable than the disadvantage and undesirable shrinkage of the tissues following the use of cocaine. That the shrinkage of the tissues caused by cocaine is at times a disadvantage is illustrated by the following case: A lady of a somewhat nervous disposition, suffering from obstructed nasal breathing, was recommended to Dr. Guttmann for treatment. On examination, Dr. Guttmann found a hypertrophy of the posterior tip of the inferior turbinate body. The lady being very sensitive, he applied some cocaine solution to the nostril in which he intended to operate; but on introducing the cold snare he found that the tumor, which was previously so evident, could not now be seized with the instrument. A second examination showed him that the reason for this was the almost complete shrinkage of the tumor caused by the cocaine. Had holocaine been the anesthetic, he should have been spared the vexation of having to ask the lady for a second visit for the performance of the operation.

Besides the well known bitter taste and disagreeable, choking sensation which cocaine produces when applied to the nose and throat, it also produces a sensation of dryness which causes the patient to hawk so much that very often profuse hemorrhage results. All these undesirable phenomena are entirely absent when we employ holocaine. Obviously, then, holocaine is to be preferred to cocaine, not only when we wish to avoid the shrinking effect of cocaine, as in the removal of granulations from the ear, of hypertrophies of parts of the turbinated bodies, of small polypi in the ear, throat, nose, etc., but also when we wish to avoid the other disagreeable effects of cocaine when operating on the aforesaid organs. It must be evident to all that holocaine is a valuable substitute for cocaine in persons who have unfortunately become victims of the cocaine habit, and in those exposed to the same danger from the frequent use of cocaine for the amelioration of some complaint.
In conclusion, Dr. Guttmann wishes to say that during the last year he has employed holocaine instead of cocaine in about a hundred and fifty operations, and has never observed the slightest toxic or alarming manifestation. According to the investigations of several writers, it is not advisable to use holocaine hypodermically. Although holocaine will never entirely replace cocaine, yet it will frequently be of equal service, and under certain circumstances will even be preferred to it.

SOME REMARKS UPON OBSTETRICS IN PRIVATE PRACTICE.

Dr. J. Clifton Edgar, in an article with this title in the New York Medical Journal of June 17, 1899, asks the following questions, and then answers them:

Shall the obstetric outfit be prepared by the patient or nurse, or shall it be procured already prepared from some dealer in surgical dressings?

A further question naturally suggests itself, namely, of what does the obstetric outfit today consist?

Aside from the "mother's outfit," meaning the clothes she will need during her lying-in period, and the "baby's outfit," including, if possible, a "baby basket," the obstetric outfit should at least include the following articles:

1. A douche-pan, preferably square and of enamel or agate-ware.
2. Two ordinary rubber blankets, or two pieces of rubber sheeting, one one yard square and the other two yards square.
3. Three or four dozen soft napkins for vulvar dressings, or the same number of vulvar pads from a surgical-dressing dealer.
4. One or two pounds of sterilized absorbent cotton, or twenty-five yards of cheese-cloth or sterilized gauze. This for sponging.
5. Six abdominal binders of soft muslin or muslin, eighteen inches wide, and preferably made to fit the figure at the sixth month of gestation.
6. Two hand brushes.
7. Some old linen for the baby's eyes and mouth.
8. Four ounces of tincture of green soap.
10. Seven ounces of chloroform.
11. Four ounces boric acid, powdered.
12. One tube of sterile white vaselin (for the baby).
13. Small and large safety-pins and bank pins.

If there is no nurse available before labor sets in, and it is necessary for the patient to see to the cleansing of the above articles, she may be instructed to pin the douche-pan, rubber sheeting, and hand brushes separately in coarse kitchen towels and boil for half an hour in an ordinary wash-boiler. The articles so boiled are then dried without removing the towels, put away, and not opened until the time of labor.

The soft napkins, if these are to be used for vulvar dressings, should, freshly laundered, be pinned, half a dozen in a package, in coarse kitchen towels and put away until the onset of labor. The nurse is then instructed to sterilize one package at a time by placing in the oven until the outer covering is scorched. For sterilizing instruments and dressings in the oven of the kitchen range, one only requires a thermometer graduated to 200° C., so as to prevent the temperature from rising too high, and to make sure that 140° C. is obtained. The absorbent cotton, the old linen for the baby's eye, and the cheese-cloth are treated in the same way, the latter two being cut up into convenient pieces and sterilized as needed. It is sufficient that the abdominal binders be thoroughly laundered and pinned separately in freshly laundered towels until needed.

Further articles to be in readiness at the time of labor, and obtainable in most households, should include:

1. Arrangements for an abundant supply of hot water.
2. A bowl for vomited matter.
3. Two c'lean earthen-, agate-, enamel-, or paper-ware bowls for hand cleansing.
4. A clean bowl for the placenta.
5. Three pitchers—one for boiling water, one for cold boiled water, and one for mixing antiseptic solutions.
6. A clean cup or tumbler with boric acid solution, and gauze or old linen wipes for the baby's eyes.
7. A half-dozen freshly laundered old linen sheets to serve as bed-pads.
8. An abundant supply of freshly laundered sheets and towels.
9. A change of nightclothing, warmed, for the mother.
10. A warm blanket to receive the baby.

Of these articles the four bowls, the cup, and the three pitchers should be scrubbed with soap and water and boiled in a wash-boiler, or at least scalded out.
It is sufficient that the old sheets to be used as bed-pads and the usual bed-sheets and towels are freshly laundered.

For special cases, however—for example, breech presentations—it is desirable that half a dozen towels shall be sterilized by boiling or by dry heat in the oven, as described above.

It will be noticed that the time-honored douche-bag and tube have not been referred to, and this is because we do not employ douches except for a positive indication, and further, because we believe these articles should be part of the physician's obstetric outfit, sterilized and cared for under his direct supervision. There is no reason why a patient, be she ever so wealthy, should purchase an instrument which may be needed, and, like other surgical appliances, should be used, only by the physician himself, or under his direct supervision. Dr. Edgar says it is his firm conviction that, both from the clinical and bacteriological standpoint, an intra- or postpartum douche, be it never so carefully administered, carries with it a distinct risk of infection, and involves a responsibility which should not be lightly assumed.

Most, or all, of the articles contained in the above list can to-day be obtained, sterilized in their final wrappers and ready for use, from many of the dealers in surgical dressings, at prices for the outfit varying from four to thirty dollars.

These obstetric outfits, cleansed and sterilized, are usually packed and sealed in a neat box, thus allowing the contents to be kept intact until needed.

The contents of these outfits vary somewhat in detail, but the following list contains the essentials:

1. Agate-ware (square) douche-pan.
2. Sterilized bed-pads.
3. Sterilized vulvar pads.
4. Sterilized absorbent cotton.
5. Sterilized absorbent gauze.
6. Two pieces of rubber sheeting or two ordinary rubber blankets—one for permanent labor bed and the second for the draw sheet.
7. Abdominal binders.
8. Glass and rubber catheter.
9. Scrub or hand brush.
10. Sterilized tape for cord.
11. Sublimate tablets; boric acid, powdered; chloroform; ergot; borated talcum powder; soap; tube of sterile vaselin; safety-pins.

A CASE OF ACETANILID POISONING FROM EXTERNAL ABSORPTION IN AN INFANT.

THOMPSON WESTCOTT reports the following case to Pediatrics of June 15, 1899. He believes it is of value as offering another instance of the facility with which acetanilid, when externally applied, may find its way into the circulation and produce toxic effects.

The patient was a female infant, about four months old, the child of a physician, through whose request Dr. Westcott saw the case in the later stages after recovery was already assured. She was a well developed, fat little baby, nursed entirely upon the breast, and during the hot weather of last summer, at Atlantic City, she had suffered severely from the heat, perspiring freely and becoming chafed in the folds of the groin and the creases of the thighs. In some of these localities the intertrigo had become almost eczematous. For the treatment of this condition a dusting powder of pure acetanilid had been ordered and used only once when the alarming symptoms developed. About ten o'clock on the morning of that day the powder had been dusted upon and rubbed over the affected surfaces. The baby was then nursed and put to sleep in her crib. When taken out at 1 P.M., the time for her next nursing, the mother noticed that the skin had a peculiar grayish pallor and the lips were bluish, though the surface temperature did not seem lower than usual. She nursed well, and went to sleep again at 2.30 P.M. The skin was waxy; the mucous membrane of lips and tongue more deeply cyanotic, and the face drawn and pinched-looking. At 3.30 P.M. the appearance was still unchanged, and the child was in a heavy slumber, from which she could not be easily aroused. There was said to be no sweating, and at the time the father first saw her, about 5 P.M., she had improved somewhat in appearance; the cardiac action and respiration were not appreciably disturbed. A few drops of whiskey was then given hourly, and when Dr. Westcott saw her, about 6.45 P.M., the cyanosis was passing off and continued to do so appreciably, as he watched her for fifteen or twenty minutes. She could be roused easily, but was disposed to lie quietly, and readily fell asleep again. The pupils were normal, and the pulse and respiration showed no marked alteration. Recovery was thenceforth uninterrupted, without demanding further treatment. The remains of the powder had not been removed until the father saw her, some four
or five hours after signs of poisoning were first noticed, and when improvement had already begun; so that it seems likely that continued absorption of the drug had been checked by the process of crusting over the exposed surfaces of the derm.

Since the introduction of acenanilid as a dressing for wounds by Harrel in 1893 (Medical News, October, 1893) numerous instances of toxic absorption have been recorded. Less frequently have like results followed in more superficial lesions of the surfaces of the skin.

Newton (Medical Record, March 7, 1896) records the case of a child with extensive burns of the face, arm, and leg. The central portions of the wounds were sprinkled with acenanilid, between twenty and forty grains being used on five occasions in nine days. When this dressing was applied on two successive days there followed in four hours a condition approaching collapse, marked by extreme cyanosis, weak and rapid pulse, and dilated pupils. Recovery was gradual, cyanosis and coldness persisting for several hours.

Briggs (Occidental Medical Times, October, 1895) observed mild toxic symptoms after use of the drug as a dressing for a circumcision wound in an infant a week old.

Carmalt (Yale Medical Journal, 1896, p. 131) produced cyanosis in a girl of eighteen years by using the powdered drug upon a profusely suppurating ulcer.

Rook (Journal of the American Medical Association, 1896, xxvi, p. 239), records two serious cases—one in a baby four days old with erythematous inflammation of the skin, nates, thigh, and groin, for which several applications of a powder composed of equal parts of acenanilid and bismuth were used. Death occurred within eighteen hours after the powder was first applied. In the second case, an infant two days old, Rook used the drug for erythema of thighs and nates. Intense cyanosis was observed about twenty-four hours after the first and only application, but the child recovered.

Snow (Transactions American Pediatric Society, vol. ix, 1897, p. 39) has seen severe symptoms from absorption of the drug from the umbilical stump after detachment of the cord on the seventh day, about sixty grains of the crystals having been used once. Absorption was slow, and symptoms did not appear until after the ninth day, fully sixty hours after the drug was applied.

In the case here recorded the actual amount of surface capable of directly absorb-
wall tends to check vomiting; these measures counteract or remove the local irritant. In view of these considerations, it would seem to be right to give the patient his breakfast before administering the anesthetic. It would not be wise to allow him to distend his stomach, but it does not seem to matter how near the administration the meal is given, provided that the anesthetist will not let him be sick on the table.

Certain medicinal measures may be taken to prevent the onset of sickness. First, as already mentioned, we may exhibit local anesthetics. Dr. Maclaren suggested a capsule of cocaine, $\frac{1}{14}$ grain; menthol, $\frac{1}{4}$ grain; and carbolic acid, $\frac{1}{4}$ grain. This was given as soon as the patient came out of anesthesia. Sixteen patients were treated in this way. Of these, four were sick. This equals twenty-five per cent. These patients had been prepared in the ordinary way. As already mentioned, in those similarly prepared, who did not get these capsules, the percentage of cases sick was 35.2. This is a gain of ten per cent. Cocaine alone in capsule was tried also, but the results were not good. Sixteen patients were given one-sixth grain; ten were sick. This equals a percentage of 62.5 sick. The use of pepsin has been recommended by some surgeons as a preventive against chloroform sickness. The result, as Ross has found it, happens to be the same as that obtained when cocaine alone was used. Sixteen got it; ten were sick. It is recommended in doses of two drachms to four drachms ten minutes before the administration of chloroform, and again as soon as the patient can swallow.

If sickness has come on, in many cases it will soon stop; but if it has gone on for a few hours something must be done, as the patient soon becomes worn out. First, on the ground that there is in the stomach a local irritant, we get the indication to remove this, to practice lavage of the stomach, as recommended by Greig Smith. This may be done by the stomach-tube, but much more easily by giving the patient two large breakfast cups of weak tea, without sugar or cream. Almost at once the patient will vomit a large quantity of fluid, and will then often turn round and go to sleep. This seems to be a very good plan for stopping chloroform sickness. It always succeeds. It is liked by the patients. The remedy can be got anywhere.

A second indication is the exhibition of stimulants, on the ground that vomiting is due partly to faintness. Brandy in teaspoonful doses has often a very beneficial effect. Dr. Ross thinks, however, that it is only temporary, lasting two or three hours.

Morphine is recommended in many books; possibly its effect is deceptive. A full dose of morphine will of course stop vomiting, because morphine checks peristaltic movement. But when the effect of the drug passes off, the condition of vomiting is apt to be reestablished. Indeed, it is common for patients after operation, to whom morphine had been given for pain, and who had not been sick prior to its exhibition, to vomit on awakening from the morphine.

There is a class of cases where the patient continues for some days to be sick once or twice a day. It will be found that an evacuating enema will often check this. Sinapisms over the epigastrium are in all cases useful. Cresote in minim doses was tried in four cases; it did not appear to be of advantage in any of them.

THE TREATMENT OF RENAL DROPSY.

NESTOR TIRARD in the Edinburgh Medical Journal for June, 1899, tells us that in the treatment of renal dropsy due to acute nephritis there are three dangers to be kept well in mind. These are: (1) The immediate danger of suppression of urine; (2) the danger of interference with respiration and with the circulation; (3) the more remote danger of chronic renal changes, which will in all probability result from the accumulation of effused blood around the capillaries of the glomerulus and within the renal tubules.

In considering these three sources of danger it will be found that the most satisfactory treatment is that by which the dropsy is reduced most rapidly; and indeed, though Dr. Tirard has headed this paper “The Treatment of Renal Dropsy,” he says it is necessary to remember that to a large extent in the treatment of renal dropsy must be included a consideration of the general management of acute and chronic nephritis.

The treatment of the dropsy of acute nephritis must include measures which will meet the threefold dangers above indicated; and since the most imminent danger is that resulting from suppression, this demands the first consideration.

To obviate the dangers of suppression, it is necessary to restore the interrupted functions of the kidney as early as possible, so as to favor the renewed elimination of nitrogenous waste. Since, however, the arrested
action is associated with extreme engorge-
ment of the renal vessels, any measures cal-
culated to increase this engorgement must be
deprecated; and our efforts must primarily
be directed towards the relief of the results
of the engorgement, and at the same time to
the removal of the existing overdistention
of the renal vessels.

The three main channels for the removal
of fluid from the blood-vessels are the skin,
the intestine, and the kidneys; and their re-
spective excretory functions can be stimulated
by diaphoretics, by hydragogue purgatives,
and by diuretics. The employment of diu-
retics is contraindicated in the early stages
of acute nephritis, since the majority of
these remedies would cause an increase in
the caliber of the renal vessels, and would
thus promote the engorgement which it is
desirable to relieve. Hence, so far as re-
medial measures are concerned, at the com-
 mencement of treatment, we are almost
entirely dependent upon diaphoretics and
hydragogue purgatives.

Dr. Tirard says he is well aware that some
observers, and notably Sir William Roberts,
advocate the early use of drugs intended to
render the urine alkaline, hoping in this way
to prevent the coagulation of blood or of
albumin within the tubules. When such co-
agulation arises it undoubtedly adds largely
to the risks of the subsequent development
of chronic nephritis, and coagulation is cer-
tainly more likely to occur when the urine is
highly acid. It has also been urged that not
only remote but also immediate dangers are
diminished by this form of treatment, and Sir
William Roberts states that in no instance,
where the urine has been rendered alkaline
during the first week of the complaint, has he
observed the more severe uremic symptoms
or secondary inflammations. To effect this
object it is necessary to employ either potas-
sium acetate or citrate, or the salts of sodium,
which are converted into alkaline carbonates
within the body. These compounds have,
however, a powerful diuretic action, and Dr.
Tirard considers, therefore, that their use
before the initial engorgement is relieved is
not devoid of risk. They are valuable when
an increase in the urine eliminated, and a
decrease in the blood-red color indicate that
the primary engorgement has subsided, and
that the circulation through the kidney is
again tending to the normal condition; but so
long as the urine is blood-stained and scanty,
he prefers to rely upon other measures for the
relief of the more urgent symptoms.

By securing rapid action of the skin we are
generally able to insure diminution of dropsy,
and thus afford relief from severe and per-
sistent headache, which is so frequently a
prominent symptom. The action of the skin
may be favored by baths, by drugs, and to
some extent by copious draughts of liquids.
The measures adopted must to a great extent
be determined by the circumstances of the
patient, and by the amount of nursing assist-
ance which is available; but a little ingenuity
will readily overcome difficulties, and permit
the early employment of almost any desired
form of treatment. Rapidity of action may
often be secured by the use of the hot-air or
vapor bath, and it is in this connection that
the greatest amount of ingenuity will be
required. In a well-appointed hospital it is
easy to administer a vapor bath, since the
necessary apparatus is always at hand. This
consists of a large steam-kettle, which is
placed at the foot of the bed, with its tube
projecting a short distance through a wooden
partition into the space at the foot of the
bed. The bedclothes are raised around the
patient by a large cradle, similar to that em-
ployed in the surgical treatment of fractures
of the lower extremity. Two of these cradles,
if necessary, may be used, so as to increase
the space surrounding the patient, and the
cradle is then covered with blankets which
are closely fitted round the patient's neck, so
that his body is completely surrounded with
warm, aqueous vapor. It is necessary to fix
the tube of the steam-kettle in a position
where it can by no possibility come into con-
tact with the patient's limbs, since otherwise
considerable damage may be done, the
cutaneous sensibility of dropsical patients
being so greatly reduced that severe blister-
ing may result before there is any complaint
of discomfort.

In cottages the vapor bath may sometimes
be employed by seating the patient in a chair,
under which a lamp with a large wick is al-
lowed to burn, the patient being surrounded
with blankets. This proceeding is, however,

extremely hazardous, as there is danger of
the lamp flaring and setting light to the
woodwork, or to the bedclothes. But, inde-
dependently of this danger, this form of vapor
bath is objectionable, since it requires a pa-
tient to be placed in an erect posture when,
in all probability, he is in a condition of ex-
treme weakness; and dropsical patients are
notoriously heavy and difficult to move. The
vapor bath, however, may, with a little in-
genuity, be easily arranged, even in a cot-
tage; the bedclothes may be temporarily raised sufficiently by low stools, such as are to be found in most country cottages, or, if these are not available, a few barrel hoops and a pole may be tied together so as to form a good imitation cradle. Yet even then there is the difficulty of arranging the lamp with safety, and in general it is felt to be easier and safer to promote the action of the skin by the use of wet packs or by warm baths; of the two, the wet pack is far more easy to manage, since it involves no apparatus, and entails less movement of the patient. The wet pack may be either hot or cold, and it does not appear to be of much importance which form is adopted. If the cold pack is employed, it is only really cold at the moment of its application, since, as a rule, the cold speedily excites a strong reaction which serves to warm the sheet and to surround the patient with warm vapor. On the other hand, the hot pack may sometimes be applied injudiciously warm, and thus cause pain, or even damage to the skin by scalding, or it may produce a sense of cold as the temperature falls more nearly to that of the body; but, as in the case of the cold pack, the resulting vapor which envelops the body will speedily be formed.

In applying the pack, the patient should be completely undressed, or should only wear a thin cotton night-dress, and the wet sheets should be wrapped round and then quickly covered with successive layers of blanket, so as to envelop the patient completely with the exception of the head, care being taken to leave no portion of the damp sheets projecting beyond the blankets. The time spent in the wet pack must, to some extent, vary according to its effects. Twenty minutes or half an hour is usually sufficient to induce copious perspiration, and when the action of the skin has been well started, continued diaphoresis will follow after the removal of the pack. When the sheets are removed the surface should be quickly dried with warm towels, and the patient should again be enveloped in warm blankets.

If, however, there are facilities for employing a warm bath, and if the patient is sufficiently well to be able to move readily from the bed to the bath and back again, the bath may be used, the water being at a temperature which can be tolerated with comfort by the hand and arm of the nurse; but after the bath it is desirable to promote further diaphoresis by wrapping the patient in warm blankets, directly after he has been quickly dried.

When any one of the foregoing measures is being adopted, free perspiration may be encouraged by allowing the patient to drink copious draughts of water from time to time, while further action may sometimes be encouraged by the administration of full doses of liquor ammonii acetatis. It frequently happens, however, that during the first or even the second employment of any of the above measures, the skin does not act very satisfactorily, and the practitioner must then be guided by his judgment and by observation of the patient as to further treatment.

In young adults, when the dropsy is the result of acute nephritis, it is ordinarily advisable to employ hydragogue purgatives, and to repeat the use of the hot bath or other diaphoretic measure some twelve or twenty-four hours later. On the other hand, when the subject affected by renal dropsy is a man of middle age or of advanced years, it will ordinarily be found that if the bath fails to afford immediate relief, it commonly produces much headache, and, indeed, it may have to be discontinued when the skin does not act, or acts but feebly. Since, however, there are great advantages in the free diaphoretic action of the skin, it is desirable in some cases to endeavor to stimulate diaphoresis by the hypodermic use of pilocarpine. It is sometimes found that relatively small doses of the pilocarpine nitrate will suffice to initiate diaphoresis, which can then be increased by the use of the wet pack or of the hot bath. This drug, however, requires to be employed very cautiously, since although by its use considerable diaphoresis may be produced, it also has the power of promoting excessive action of the salivary glands, and apparently also increased secretion from the bronchial mucous membrane; therefore it is not to be employed with patients who are so far comatose that they are unable to expectorate, nor should it be used with those who are already suffering from edema of the lungs, or when there are indications of cardiac weakness.

If diaphoretic measures afford little relief, or if the relief appears to be purchased at the cost of great suffering, it is well to continue the use of hydragogue purgatives, such as the compound jalap powder of the Pharmacopoeia, or of a mixture of jalap powder with scammony powder; and Dr. Tirard has observed that the action of these hydragogue purgatives will frequently be followed by considerable diminution of dropsy, and by gradual increase in the amount of urine that is passed.
In the dropsy of acute nephritis the use of diaphoretic measures is scarcely as imperative as it is in cases of dropsy associated with acute attacks occurring in the course of chronic nephritis. In acute nephritis, especially in the form resulting from scarlet fever, free purgation is generally followed by rapid diminution of dropsy.

**States of Overexcitability, Hyper-sensitiveness, and Mental Explosiveness in Children, and Their Treatment by the Bromides.**

Clouston writes on this subject in the *Scottish Medical and Surgical Journal* for June, 1899. After discussing the general conditions named, Dr. Clouston says that so far as his experience of drugs goes, he has found the bromides by far the most effective in restraining normal nerve cell action from assuming pathological forms. They must be given judiciously and with reference to the age of the patient, the acuteness and the nature of the symptoms, and the effects of the drug in each case as seen by a skilled observer. They must often be given fearlessly in large doses up to the point when the symptoms of bromism are beginning to show themselves. One thing is certain, if they are to do any real good, they must be given for long periods. A few doses or an intermittent course of them at first is of little good, and when they have done their work they must be gradually discontinued and not suddenly stopped. The general health, the weight, and the progress of the child’s nutrition must be most carefully observed all the time they are given. Dr. Clouston does not advocate bromide treatment alone—far from it; he gives tonics and food medicines at the same time as the bromides, and the diet must receive never-ceasing attention. He thinks milk will be found the sheet-anchor in dieting all such neurotic children. Environment, too, fresh air, suitable amusements, companionship, control, employment must be looked to, and the schoolmaster must be regarded for the time as an aid to treatment and so under the doctor’s orders.

Such an explosive brain need not remain uneducated, but it must receive its education in a physiological and medical fashion. Education must submit to be one of the factors that go to develop such an organism on sound lines, so that the greatest possible result of work compatible with health and happiness may be attained in after life. In a few cases, if there appear very acute phases of the illness, a few grains of sulphonal (from five to ten) twice a day, combined with the bromides, Dr. Clouston has found very useful by accentuating the effects of the latter. The effect we aim at is to diminish undue cell catabolism and reactivity in the cerebral cortex without interfering with brain anabolism or general body development. And we keep in mind that such effect must be carefully watched so that it does not go too far.

---

**Notes on the Treatment of the Diseases of the Nervous System.**

Graham Brown, of Edinburgh, writes in the *Scottish Medical and Surgical Journal* for June, 1899, upon this theme. He first deals with the pathology of syphilitic nervous disease, and then goes on to point out that the poison of syphilis frequently attacks the nervous tissues and produces far-reaching effects. In combating these lesions the antisyphtillic treatment requires to be of the most thorough kind, and it is usually advisable to employ both mercury and iodide of potassium.

Let us take for an example some specific cord affection such as syphilitic myelitis. How are these remedies to be administered in this case? Now, it is no doubt true that the action of mercury can be attained by administration by the mouth. But in doing so, if we are to obtain the full effect of the drug, we have to give doses which are very liable to produce gastrointestinal irritation and salivation. So much is this the case that if we give even so mild a preparation as gray powder for any length of time, we have to combine some opium with it so as to control its action on the bowel. This addition of opium is, in Dr. Brown’s opinion, inadvisable, and yet we must secure a thorough mercurial action. He believes that in these cases of syphilis of the nervous system the mercury should not be given by the mouth. Two other methods are open to us—we may have the mercury rubbed through the skin, or may give it hypodermically. Of these, the method by friction is usually to be preferred.

In such a case, then, as we have supposed, if we resort to the method of inunction, directions should be given that from thirty to sixty grains of mercurial ointment be rubbed into the skin daily, a different part of the body being selected on each occasion. The patient may begin, for example, with
the right arm, then the left arm, the right thigh, the left thigh, and then da capo. A square of linen rag is taken, sufficiently large to cover amply the area of skin to be rubbed, and on it a portion of the quantity of ointment to be used is placed. With this the patient is instructed to rub the skin vigorously, adding from time to time a little more of the ointment until the whole quantity has been rubbed in. This operation should take from ten to fifteen minutes. Thereafter the square of rag is to be laid over the skin surface, covered with a layer of cotton-wool, and retained by means of a light bandage. The inunction is to be made at night, and the patient sleeps with the rag and bandage so adjusted. In the morning the vigorous application of soap and hot water will remove any traces of unabsorbed ointment.

In certain continental watering-places, where the treatment of syphilis is specially attended to, the inunctions are made by means of a glass instrument, shaped like a handle, and bearing on one end a hemispherical surface of ground glass, with which the ointment is rubbed in. The inunctions are made by a skilled rubber, about an hour after the patient has left a warm bath. Dr. Brown thinks, however, that the method of inunction which he described first is the better for such cases as those we are now considering.

Such inunction as this should be made daily for a fortnight, or if possible three weeks. There should then come a pause of a week, and, if no stomatitis has developed, a new series of frictions may then be entered on. After the second series of inunctions is completed a pause of a month’s duration is advisable, after which the treatment should be recommenced. To be complete, these series of inunctions should extend (with intervals of increasing length) over a period of three years. The necessity of taking care of the teeth and gums during such treatment as this is well known, and it is advisable to use a mouth-wash of chlorate of potash.

While Dr. Brown believes that as a rule the method of inunction is to be preferred, there are some cases in which it may be advisable to administer the mercury hypodermically. When the symptoms are severe, and the need for mercurial action is pressing, then the subcutaneous method, which is more rapid and energetic in action than inunction, is to be preferred. It is not, however, without its inconveniences. It is painful, and if due care is not taken much induration and even abscess formation may result.

The syringe used must be carefully sterilized. The needle, which should be of platinum, is to be heated in a flame just before use, and cooled in carbolic oil. The injection is best made in the gluteal region, and the solution should be injected deeply into muscular fiber. The skin is to be carefully cleansed before the operation.

Various preparations of mercury have been made use of for hypodermic administration. Gray oil has been much used, as well as calomel in vaselin, but neither of these preparations is to be recommended.

The red iodide (mercuric iodide) is frequently employed for injection. With the aid of a little iodide of sodium it is readily dissolved in the proportion of one grain in sixty-four minims of distilled water. Of this solution from two to six minims may be injected. An even better preparation is that of Panas:

Mer. uric iodide, 0.4 grammes;
Sterilized olive oil, 100 Cc.

The oil is purified by washing with distilled water, and, after separating, it is again washed with absolute alcohol. It is finally sterilized. Of this solution one cubic centimeter (nearly seventeen minims) contains about four milligrams (one-tenth grain) of mercuric iodide.

Delpech’s solution for hypodermic use, which is much employed in Paris, consists of an ammoniated peptone of mercury of the following composition:

Hydrarg. perchlor., 10 grammes;
Peptone (dry), 15 grammes;
Ammon. chlorid., 15 grammes.
Misce.

This preparation is to be dissolved in distilled water, or preferably in glycerin, in the proportion of 40 centigrammes in 30 grammes.

There is, finally, sozo-iodol-mercury, a preparation which has recently come into some vogue for intramuscular injections in syphilis. Of this substance 2½ grains is to be dissolved, along with five grains of sodium iodide, in 100 minims of distilled water. The resulting solution may be given hypodermically in doses of ten minims.

During the greater part of this period iodide of potassium should also be given, the dose depending on the individual, but being in any case as large as can be borne. It may be begun with thirty or forty grains in the day, and rapidly increased as far as seems advisable in the particular case being treated.

In cases in which the iodide has to be ad-
ministered for long periods, use may be made of a preparation called iodalbacid by its discoverer, Dr. Blum, of Frankfort. It is an iodine-albumin (analogous to iodo-thyrin), formed by the action of iodine on moist albumin. When taken internally it readily breaks up, liberating its iodine (of which it contains about ten per cent), and not producing the disagreeable effects sometimes seen after the exhibition of potassium iodide. Iodalbacid should not be used in cases in which a rapid action is desired. In these iodide of potassium is to be preferred. But for the more chronic cases it has been found very useful. It is freely soluble in water, but is best given either in cachets or in the form of tablets. The quantity which should be administered daily is from three to six grammes (45 to 90 grains) in divided doses.

THE TRANSPLANTATION OF A HUMAN OVARY.

Dr. James H. Glass, in the Medical News of April 29, 1899, records an interesting case. A young woman who had had a double oophorectomy performed some two years previously applied for relief from the train of symptoms, lapse of sexual instinct, mental depression, insomnia, giddiness, palpitations, heat flushes, pelvic pains, et hoc genus omne, which are not uncommon sequelle of that operation. General treatment proving of no avail, on May 11, 1898, ventrofixation was performed. A second patient, aged seventeen years, married, having suffered serious injury during parturition, which had resulted in such deformity that future child-bearing would inevitably entail Cesarian section, it was decided to render her sterile by removal of the tubes and ovaries. On May 14 both patients were, with their own consent, anesthetized together, with the view of transplanting the healthy ovary about to be removed from the one woman into the peritoneal cavity of the other. The healthy ovary, immediately on removal, was placed in gauze kept moist with warm normal salt solution. When the first operation was completed, the vagina in the other patient and the connective tissue down to the cervix were incised. The latter was then stripped up to the peritoneum with the finger, and this membrane carefully raised from its attachments to a point approximating the normal position of the ovary. Oozing was controlled by compresses of hot saline solution, the ovary anchored in position by closing, with two tiers of fine cumol catgut, the canal through which it had been introduced, and the vagina lightly packed with silver gauze. The recovery was uninterrupted. After six days a condition of sexual erethism lasting for several days and accompanied by erotic dreams occurred. After sixteen days menstruation began and lasted two days. It was then absent until December, when it again appeared and was normal in every way. Eight months after the transplantation the patient had regained her equilibrium, and was apparently quite well and healthy. The value of this observation appears to be considerable; for while much of the patient's relief may possibly be attributable to the ventrofixation, the return of the sexual instinct, the recurrence of the menses, and the improved metabolism would appear to be undoubtedly due to the transplantation of the ovary.—New York Medical Journal, May 6, 1899.

A SIMPLE METHOD OF REDUCING DISLOCATIONS OF THE SHOULDER BY MANIPULATION.

Miller (Scottish Medical and Surgical Journal, May, 1899) contributes this paper because, in the first place, he finds that on all hands there is a tendency to describe and speak of Kocher's method as if it were the only method of reducing dislocations at the shoulder-joint by manipulation. In the second place, he has for more than twenty years employed and taught a method which is simpler, and in his hands has proved unfailling. Thirdly, a few months ago a country practitioner told him that he had reduced a dislocation of the shoulder without chloroform, in a strong man, by this method, which he remembered to have seen the author employ in the Infirmary. The dislocation was a day old, and had resisted attempts made with the heel in the axilla.

In the dislocated position the articular surface of the humerus is completely displaced from the glenoid. When, however, the arm is lifted upwards into a position at right angles to the body, the smooth articular surface of the humeral head is brought very near the smooth glenoid surface. The two may even be brought slightly in contact, when, one can imagine how easily, the head of the humerus may be made to glide back into position. Many authorities mention how mere elevation of the arm has reduced dislocations that were very recent. Perhaps some spontaneous reductions may occur in this way.
Another result from this elevation of the arm is that the locking of the neck of the humerus on the edge of the glenoid is undone. This being so, it requires only slight internal rotation of the humerus in its long axis to make the head of the bone glide into its normal situation. Dr. David Waterston, in a recent pamphlet on Kocher’s method, extracted from the British Medical Journal, says that reduction is prevented by the locking of the neck of the humerus and glenoid edge described by Caird, and that it is the inward rotation that “disengages the indent from the tip of the glenoid.”

The experience of the author is that reduction by this method occurs without any snap or jerk, and that often the operator is unaware of the reduction (as also the patient) till the filling out of the deltoid region and free movement of the joint prove the reduction to be complete.

The author describes the process by manipulation more exactly. Suppose a recent case. The patient being seated on a chair, the surgeon stands at the injured side (say the right) and takes the arm in both hands, one (the left) being above the elbow, the other (right) above the wrist, the arm being bent to an L at the elbow. An assistant stands at the patient’s other side and steadies the scapula with both hands.

The surgeon then (having of course made sure that there is a subcoracoid dislocation) gently and slowly elevates the arm, making traction outwards from the body, at the same time assuring the patient that what he is doing will not be very painful, and that it is not the actual reduction but merely a preliminary. If the patient should resist, then the surgeon may wait for a while, or administer an anesthetic.

When the patient has ceased to resist the arm will come slightly towards the surgeon; then is the time to rotate the humerus by dropping the hand, and the head of the humerus will glide into position. If the dislocation has been “out” for some time—a day or two—then the patient should be laid on a table, and an anesthetic administered. The same procedure as above is then gone through. If reduction does not occur at once, the humerus may be freely circumducted, so as to break down any adhesions that may have formed, and to widen the opening in the capsule.

The author repeats here that he has never failed by this method, except in one or two cases in which every other means failed and the knife had to be called into requisition. On the other hand, this method has succeeded in his hands and in others' when other procedures had failed.

In one case he succeeded single-handed. The patient was a stout old man. The author found him in bed. He turned him on his sound side, got up on to the bed and stood over him, then grasped the dislocated arm by the elbow, and extended the arm from the side. The head of the humerus quietly glided into its place, much to his satisfaction as well as his patient’s.

Reduction may be aided sometimes by a maneuver which is recommended by many authorities, viz., pressure in the axilla, with thumbs or fingers on the head of the humerus (Avicenna's method).

VAGINAL ABLATION IN PELVIC INFLAMMATIONS.

Pryor (American Journal of Obstetrics and Diseases of Women and Children, May, 1899) enters an earnest plea, backed by one hundred operations without a death, for the vaginal operation in pelvic inflammations. Vaginal extirpation of the ovaries, tubes, and uterus is accomplished by the formation of four pedicles. These pedicles are secured by forceps and slough; therefore they must be treated extraperitoneally. The very essence of the vaginal operation is the extraperitoneal treatment of the stumps. The vaginal mucosa is incised at the posterior fold, over the point where the peritoneum is reflected from the uterus. Laterally this incision reaches the level of the sides of the cervix. The anterior incision should be made, not in the dense cervical tissue, but in the loose reticular tissue between the uterus and the bladder. Both the anterior and posterior incisions are crescentic in shape. Their ends do not meet, but between them a strip of mucous membrane, an eighth of an inch in width, is left. The value of this will be appreciated at a later step. The author finds that in most cases he can bore into Douglas's pouch with the finger, and always either does this, or at least dissects the tissues up as high as he can, generally using the fingers. In separating the bladder from the uterus he finds assistance from the intra-uterine traction forceps, which fix the uterus, whether the dissection is effected by means of the finger or by toothed forceps and scissors.

In this, the first stage of the operation, the author seeks no more than the liberation of
the uterus from its normal attachments, anteriorly and posteriorly. This being accomplished, he introduces his finger along the middle line of the posterior surface of the uterus as high as can be reached. In doing this attached organs are liberated only so far as will enable him to make this track. The author studiously avoids any attempt at freeing the adnexa at this stage. So far there has been no hemostasis. The bleeding which occurs is slight and comes from small anastomotic branches only. The traction forceps are now withdrawn and each lateral angle of the cervix is seized with bullet forceps. The closed, blunt scissors are inserted into the uterus to determine the direction of its canal. The anterior wall of the uterus is then split as high up as can be seen. An assistant holds up the bladder with a narrow retractor, and the author seizes each side of the cut in the uterus with Pén's toothed traction forceps. These are twisted outward, and as this is done more of the anterior wall of the uterus rolls from beneath the bladder. This is also split in the middle line, and other traction forceps are applied upon each side of the cut in the uterus as high as its angle. This progressive median section is repeated until the cornua uteri appear. When this occurs the author withdraws the perineal retractor and passes the grooved director up behind the uterus in the track his finger has made for it. The assistant not only depresses the perineum with this, but he also draws the uterus forward, so that the groove in the director may be both felt and seen above the fundus. Into this groove the author inserts the bistoury and accurately splits the uterus along the center of its posterior wall. The organ is now in halves. Still no attempt at hemostasis has been made.

It is well to consider what has been accomplished thus far. After entering the posterior cul-de-sac, an attempt to liberate the adnexa would be most difficult because of the presence of the uterus and because of the bilateral fixity. Further, any very general liberation of the adnexa, intestines, or omentum would only permit them to fall between the grooved director and the uterus, and thus render them liable to injury when the posterior surface of the organ is split.

After splitting the uterus the bilateral fixity is abolished, and each half and its adnexa are to be dealt with separately, free from any attachment to the other.

A pair of traction forceps is fastened into the fundus of each segment, and into each half of the cervix is locked a bullet forceps. The right half of the uterus is shoved up into the pelvis and the left is drawn down. This latter, being free from all fixity upon the right, will swing from beneath the bladder, so that in most cases its cavity will look directly out and the entire half of the uterus be outside the body, the cervical portion being over the perineum, and the fundal beneath the pubes. The anterior and posterior retractors are withdrawn, and no instruments pass into the vagina except the two traction forceps which have hold of the right half of the uterus. While the left segment is held outside the body, the left hand is introduced into the pelvis up to the thumb, or for a distance of nearly five inches. This will enable the index-finger to reach the pelvic brim in all cases.

Bearing in mind that whereas the hand is to one side of the uterus, it is also upon the posterior face of the left broad ligament, the author begins the separation of the adhesions. As manual dexterity controls the ease with which this can be accomplished in all suprapubic work, so also it determines the facility with which the adherent ovary and tube may be liberated through the vagina. The author states that if he were to compare the two methods, he would say that it is easier to free through the vagina all organs which are adherent below the pelvic brim. The attachment of omentum and intestines to the adnexa can be severed either by the fingers or by scissors. In the latter act it will be but necessary to hold up the bladder with a retractor. The adnexa will be found most closely applied to the posterior surface of the broad ligament and to the lateral pelvic wall. Inasmuch as the adventitious union is between the peritoneal surfaces, the separation of the agglutinated tissues proceeds along the usual "plane of cleavage."

If the dissecting fingers evacuate a pus pocket, the author states that he is secure in the conscientiousness that its contents will escape below and will not enter the higher abdominal cavity. If such an event occurs—and many pus tubes are exceedingly friable—he withdraws his hand, cleanses it, and scrubs the pelvis dry. Very rarely in these pus cases will it be found that the intestines are sufficiently free to prolapse into the vagina during the operation; but in such an event they can be kept in place by a gauze pad. The author has seldom seen a knuckle of small gut during his operations. In fact, not often is the small intestine adherent to either
the uterus or tubes, but all false attachments of the coils of small intestine are interintestinal. The author states that in his vaginal work he is well beneath all such complications and they are avoided.

When he has liberated the left adnexa he returns them and their half of the uterus into the pelvis, the uterus being under control by traction forceps. He now introduces the right hand into the pelvis and liberates the right adnexa. This is accomplished in exactly the same way as upon the left side, only he is careful to determine whether the appendix vermiformis is attached to the adnexa. If it is, anterior and posterior retractors are introduced and it is inspected. If the appendix is merely adherent it is carefully liberated without doing damage to it. By no means are all adherent appendices diseased.

After freeing the right adnexa he draws them from beneath the bladder and grasps the upper border of the broad ligament with forceps. This is applied from above downward, so that the strength of the forceps is upon the ovarian artery, and the point of the forceps down. The broad ligament is now cut to the point of the forceps, and another forceps is applied in the same way to the uterine artery. The right half of the uterus and right adnexa are removed. The two forceps are dropped and the left adnexa and half of the uterus similarly treated. When liberating the adherent adnexa the author appreciates the importance of leaving a narrow strip of vaginal mucous membrane between the anterior and posterior incisions, for, did he not do so, he might possibly rip up the cervix from the pelvic floor and thus tear the uterine artery by the forcible introduction of the hand into the pelvis. He emphasizes one feature of this method of operating — namely, the absence of all attempts at hemostasis until the two sets of adnexa are entirely free. Otherwise, in certain cases of small vagina, the forceps would be very much in the way, and in rotten tissues there would be danger of tearing them off the pedicles they hold.

Attention is also called to the method of applying all the forceps from above downward, which insures their being, together with the stumps they hold, in the vaginal vault. When the forceps are dropped those on the ovarian arteries fold the top of the broad ligament over the pairs on the uterines, and in this way the latter are prevented from touching the bladder. As the forceps are applied upon each side the halved uterus is drawn to the opposite side, in this way increasing the distance between the cervix and the ureter.

The pelvis is now wiped dry and a gauze pad is introduced. The table is tilted into the Trendelenburg position, and a careful inspection of the pelvis made for bleeding from aberrant vessels. Upon each side a strip of iodoform gauze is introduced between the forceps and the vagina. Each set of forceps is held aside by long, angular retractors, and the vagina is filled with gauze. The dressing is made to project above the points of the forceps at all points, and is snugly applied —ten or a dozen pieces, each a yard long and four inches wide, are usually introduced. The patient is lowered into the horizontal position and a self-retaining catheter introduced. The sphincter ani is dilated, for the bruising of the perineum causes spasm if the sphincter remains active, and the bowel should be open for the early passage of gases and feces.

The features of the operation, as performed by Pryor, are the liberation of all the adherent organs before any hemostasis is attempted, and the application of the pelvic Mikulicz dressing. The first is essential to the formation of the pedicles, so that they may be strictly extraperitoneal, while the latter insures the retention of these pedicles in their proper position while isolation of the field of operation and its sterilization are accomplished by the dressing.

A certain mortality from this operation is found abroad to be due to late infection occurring after the forceps are removed. This is entirely due to a disregard of the possibilities of the pelvic Mikulicz. In the first place, this dressing drains and sterilizes the pelvic pouch.

Attention is called to the fact that no pins are used to fasten the stumps outside the peritoneal sac in this operation, as is done in the old extraperitoneal suprapubic hysterectomy, but this is accomplished in vaginal ablation by the forceps for two days only. When these are removed the ovarian stumps, not being held, have a tendency to snap back into the peritoneal pouch, and Pryor is convinced that a part of the European late mortality is due to this. The application of the pelvic Mikulicz prevents this. As the first essential to a successful vaginal ablation was found to be the formation of the stumps so that they would be extraperitoneal, so the second embraces the proper annihilation of
dressings which will maintain these stumps outside the pelvis while the union between the bladder and rectum is forming.

Another attribute of the method of forming the stumps, not less important than the one mentioned, is that by it the forceps cannot touch any part of the pelvic contents, and hence fistula are not seen to follow the method advocated. Apart from the sentimental objection to an abdominal scar which is held by some women, there are several real objections to making a section of the abdomen in these pus cases. In removing pus foci through an abdominal incision they must be dragged through a cut which it is expected must close by primary union. Even to-day occasionally an abdominal wound or stitch-hole suppurates.

THE TREATMENT OF INGUINAL HERNIA IN CHILDREN.

Eccles (British Medical Journal, May 13, 1899), after a brief discussion of the anatomy of hernia in children, states that when one has to deal with a large number of congenital inguinal herniae the uselessness of the skin of sallow truss becomes only too apparent. The arguments for and against its use are: For—is simplicity; (2) its cheapness; (3) the ease with which it can be changed; (4) that it can be worn in the bath, and a dry one applied immediately afterwards; (5) that no attention is required except at the moment of changing. Against—is inefficient, and therefore a false security, except in the simplest of cases; (2) it exercises little if any pressure directly over the hernial apertures, and thus no likelihood of a permanent cure is gained; (3) it may cause excoriation.

The arguments for the spring truss are: (1) It is very efficient in retaining the viscera within the abdomen; (2) it exercises pressure directly over the inguinal canal, and thus tends to bring about obliteration of the processus vaginalis, and to enhance the prospect of a lasting cure.

In discussing the application of a spring steel truss to an infant, it may at once be conceded that an ill-fashioned instrument, covered with impure red composition rubber, one which is either too small or too large, or one that is improperly adjusted, will inevitably cause trouble. On the other hand, a well made truss, covered with pure rubber, with no seam that is next to the skin, of the right size, and properly adjusted, but seldom causes much inconvenience.

The method of measurement for an inguinal truss for an infant or young child is the same as that for an adult—that is to say, the tape should be carried round the pelvis obliquely, at the base of the sacrum behind, half-way between the crest of the ilium and the top of the great trochanter at the side, and above the symphysis pubis in front.

For a single truss the actual number of inches thus obtained is the correct size; for a double truss it is often well to add an inch to this measurement, because a double truss does not stretch at all. The adjustment of a truss at so tender an age is of the utmost importance. The inguinal canal in infancy is practically non-existent, since the deep abdominal ring lies almost directly behind the superficial, but both, it must be remembered, are placed above the level of the pubic bone, and therefore of the symphysis. In children the upper part of the symphysis pubis is considerably higher than it is generally supposed, or than it appears to be. There is, however, a distinct guide to the level required, for every child, and particularly a well-nourished one, presents a curved line running across the lower part of the abdomen, known as the fold of Venus, which accurately indicates the upper limit of the pubic bones.

The important fact to be borne in mind is that the whole of the pad of the truss must lie above this line, for if it be placed below it, the soft parts upon which it will then impinge must of necessity be compressed between the pad and the unyielding bone beneath; and, moreover, the pad would in no way tend to retain the intestine, seeing that it is placed altogether below the site of the rings through which the protrusion passes. Very soon such pressure would cause irritation, and then excoriation; but this untoward result can be entirely avoided if the truss is worn at the proper level, where it will press only on the soft parts. Here, moreover, it has but little tendency to shift its position, or to be displaced by the intentional acts of the patient.

A truss thus carefully adjusted must be worn by the child continually, day and night, sleeping and waking, crying and peaceful. Temporary removal is necessary for the purposes of cleanliness, and when this is needed it should be undertaken with the patient recumbent, and when left unguarded by the
truss, the hernial aperture should be protected by the nurse’s finger or thumb.

It is remarkable how rapidly, often within a few weeks, after the application of a truss of a proper form for a congenital inguinal hernia, descent of the viscera ceases, but such would soon recur if the truss for any reason were discontinued. Permanent closure of the processus vaginalis will be obtained in the majority of cases only after a continuous action of the pressure of a spring truss over a period of some years. A cure, therefore, can be safely predicted; but the truss should not be discarded until the child has reached the age of at least three years.

Treatment by trusses should be begun at the very earliest possible moment, as for each year of life which is passed without the use of the instrument there is a corresponding diminution in the probability of a permanent cure. It is highly fallacious to aver that a hernia in an infant will become spontaneously cured without active treatment by truss pressure. Such a result is so extremely rare that it must be disregarded in practice.

Congenital inguinal hernie in female infants are even more likely to be cured by treatment than those in male subjects. In certain instances young boys may develop very large scrotal hernie, the outcome of neglect, which may not be efficiently controlled by an ordinary truss. In such cases a rat-tail or a forked-tongue truss will be required. In all cases of hernia in the young, attention should be paid to the encouragement of muscular development by means of calisthenics.

There are two chief arguments against a radical operation with a view to a cure in the case of young children, say before three years of age. One is the strong probability that a spontaneous cure will result, provided efficient truss pressure is secured, and a proper diet is given the patient. That such a happy termination does frequently ensue is, the author thinks, the experience of most practitioners, and it is certainly not common to be given the history of a hernia having been present in infancy, then an apparent cure, and afterwards a relapse in later life. This fact would seem, therefore, to be a valid argument against the necessity of an operation.

The other argument that is put forward is that the wound formed so near the urinary apparatus in a child is very liable to become septic. The author does not think that this has much weight, for it is comparatively easy to prevent infection if the wound is made, as it should be, in the inguinal region and immediately closed with a collodion dressing of small size. It is a great mistake in all operations about this region in children to apply a bulky dressing, for such is much more liable to become contaminated than is a small one.

The following are the cases in which an operation may be advised:

1. Where a child is being properly fed, but in whom a hernia after a fair trial is not retained by a suitable truss, so that there is little or no chance of a spontaneous cure.

2. Where part of the contents of the sac are irreducible.

3. Where a truss has been worn for at least three years, but with no apparent cure of the protrusion.

4. Where a child has reached the age of at least three years, but has never worn a truss.

5. Where a herniotomy has to be performed for strangulation.

Now, it is unusual for a hernia in a child not to be adequately controlled by a proper truss. It is rare to have irreducible contents in early life. A truss generally brings about a cure. The subject of a hernia in infancy is not often in the present day allowed to go for three years without treatment, and strangulation seldom needs an operation in children; so that it will be seen that the cases where a radical operation is needed are not by any means common.

ENCYSTED VESICAL CALCULI.

W. BRUCE CLARKE (British Medical Journal, May 13, 1891) in 1891 published an account of six cases of encysted vesical calculi. Since that date he has had thirteen other cases under his care, and by the kindness of his colleagues at St. Bartholomew’s, has been able to describe eight other cases, most of which he has had the good fortune to see during their stay in the hospital, making a total of twenty-seven cases in all to form the materials for his paper.

Of the six cases that were recorded in his first paper, no fewer than three were due to pieces of bone that had found their way into the interior of the bladder from the surrounding structures. The other cases were instances of true encysted calculi, which had been formed presumably in the kidney, and then, finding their way into the bladder, had either dropped into a sacculus which was ready for their reception, or had become fixed in some depression of the bladder wall, and
had by their gradual growth formed a sacculus for themselves. It is probable that in at least one of the cases referred to in this paper, this was the way in which the calculus was formed; for when this bladder was inspected with a cystoscope two years after the removal of the stone, no trace of a sacculus was to be seen. In another case the sacculus was most likely quite independent of the stone, for stones were found on a second occasion in another part of the bladder, and the sacculus originally occupied was empty.

It has often been assumed that these sacculi are all due to what are called tunicary herniae, and depend on the pouching of the mucous and submucous coats between the bands of muscular fibers. The author, however, is convinced after an examination of numerous specimens both before and after death, that the muscular walls very often form a constituent part of these sacculi. It is, moreover, often very difficult to determine with accuracy in all cases the nature of the sac walls, owing to the inflammation which has been set up by the stone which has long lain there.

When operating on these cases there is one point which must always be considered, namely, what is to be done with the empty sac from which a stone has been removed. There is no doubt that many of these sacs, especially when prolonged attacks of inflammation have destroyed their epithelial lining, tend to contract and cicatrize of their own accord if their orifice is of sufficient size to preclude the possibility of pus stagnating in their interior. If, on the other hand, the orifice of the sac is small and contracted and the sac itself is of large size, some means must be adopted for its independent drainage, and the route which is selected must depend on the condition of the patient and the position of the sacculi. As most of these sacculi are situated near the base of the bladder, it will probably be advisable, if they demand drainage, to drain them through the perineum, and to make a temporary channel between the bladder and rectum, if this is possible.

On looking over the symptoms which these cases presented, it is difficult to single out any one sign which might be held to be of considerable diagnostic value. Cystitis of longer or shorter duration appears to have been present in every one of the cases, but as the great majority of them—namely, sixteen out of twenty-one—were above sixty ears of age, and had in addition some evidence of enlargement of the prostate gland, the cystitis was naturally in the first instance ascribed to that condition, and not to the presence of a calculus. In several undue tenderness of the prostate gland when examined per rectum, and rectal tenesmus, were marked symptoms. Only three of the cases were under forty years of age, one of them being but fourteen. The only two cases in the list between the ages of fifty and sixty had suffered from stricture; and it is noteworthy that two of the first six cases also had suffered from stricture, and were likewise between fifty and sixty years of age.

The difficulties of diagnosis were also enhanced by the fact that in several instances washing out the bladder was quite sufficient temporarily to restore the urine to a healthy condition. It is, perhaps, also worthy of note that in several instances the stones when extracted proved to be so thickly coated with mucus that even when they lay upon the table no audible note could be obtained when they were struck with the beak of the sound. This affords a ready explanation of the difficulty which may be experienced in detecting a stone in the bladder under certain conditions.

In six of the twenty-one cases no operation was performed; in most instances, because the patient's condition was too bad to admit of any chance of alleviating his symptoms. Of the remaining fifteen that were submitted to operation, four died and eleven recovered.

The fact that in less than half the cases was the existence of the stone known before the operation was undertaken certainly affords an additional argument for exploration of the bladder in those cases of cystitis which do not yield to ordinary treatment.

In one instance the patient had been castrated to relieve his prostatic symptoms, and the stone was only detected after death. It is quite possible that if his bladder had been explored at an earlier period he might have retained his testes and had his life prolonged after removal of the stone.

The author has since that time made it a rule to explore the bladder in obscure cases of enlarged prostate which remain irritable after repeated washing, and has never had occasion to regret this plan of treatment, which no doubt largely accounts for this series of encysted calculi. Even if no stone is detected, the patient usually derives great benefit from the operation, owing to the rest which is afforded to the urethra.
THE SURGICAL TREATMENT OF PELVIC INFLAMMATORY LESIONS BY ABDOMINAL SECTION.

Baldy (American Journal of Obstetrics and Diseases of Women and Children, May, 1899) states that the following is the status of the abdominal section for pelvic inflammatory lesions, as is demonstrated by his own quoted work and by that of many other surgeons:

1. The operation is the safest in this particular class of cases or almost any other to which abdominal section is applied.
2. Shock rarely enters into the case as a serious sequel; never more so than in the vaginal operation.
3. Drainage is the exception; it is the rule in vaginal work.
4. Hernia occurs in not more than one per cent of cases operated upon.
5. Women are not prone to complain of the abdominal scar.
6. The patient could arise from her bed and return to her home at as early a date as after the vaginal operation, were it considered advisable for her to do so.
7. A completed operation is always possible by the abdominal route; in a large percentage of the bad cases it is impossible by the vaginal route.
8. The technique of the abdominal operation is much more easy than that by the vagina.
9. There is less danger of damage to the hollow viscera by the abdominal route; if such injury does occur there is less danger of infection from such injury, and the damage is more readily repaired. As a matter of fact such injuries are impossible of repair by the vaginal route.
10. The mortality of the abdominal operation is all that could be desired, and no other major operation shows a better record.

TREATMENT OF EKSTROPHY OF THE BLADDER BY URETERAL RECTAL ANASTOMOSIS.

Josserand (Revue Mensuelle des Maladies de L’Enfance, June, 1899) cites statistics of this operation to the effect that of a total of eighteen cases there were but two operative deaths—one from shock, and one from infection. There were a number of cases of urinary fistula lasting but a short time, and complicated by localized peritonitis. Pyelonephritis has been observed in but a single case, namely, that of Mikulicz, death occurring in this instance four months after operation. Several cases have been followed for a period of from six to fifteen months without showing signs of kidney infection. Function was perfect in all but two cases; the urine could be retained for three to four hours, sometimes six to seven hours, and the patients could sleep all night without being inanmmoded. Tolerance of the rectal mucous membrane has always remained perfect.

The author reports the case of a child, five years old, on whom he operated. A bougie was passed into each ureter; the mucous membrane of the bladder was then circumcised by an incision carried down to the parietal peritoneum, and was dissected up. The ureters were isolated and mobilized for a distance of about one and a half inches; then the bladder was resected, with the exception of a small area placed about the ureteral orifices.

The operative region was then thoroughly sterilized anew, and a celiotomy was made an inch above the wound left by the dissection of the bladder. The sigmoid flexure of the colon was drawn out, walled off by sterile compresses, and held in place by the fingers of the assistant. A longitudinal incision was then made along the convex border of the sigmoid; into this incision the trigonum was slipped. The anastomosis was completed by two layers of continuous sutures, one mucous, the other sero-muscular, for the intestine, and muscular for the bladder. When these sutures were completed the bridge of tissue which separated the two parietal wounds was divided, and the viscera were replaced in the abdomen. The parietal wound was then closed except at the lower part, where the separation of the pubic bones made this impossible. This space was tamponed with gauze. The wound ran a fairly satisfactory course. For the first few days there was some incontinence; afterward the child could retain the bowel contents during the entire night.

SINUS THROMBOSIS SECONDARY TO SUPPURATIVE OTITIS MEDIA.

In a review of otology by Milligan (Practitioner, May, 1899) the subject of sinus thrombosis secondary to suppurative otitis media is considered, and Whiting’s summarization is quoted as follows:

1. The indications which justify an operator in ligating the jugular before exposing the sinus should be very decided and as follows: (a) The existence of chronic otorrhea;
(δ) pronounced manifestations of pyosepticemia, high fever, sudden remissions, and repeated rigors; (ε) metastases; (ζ) Griesinger’s symptom—occipital edema; (η) edema of the eyelids of corresponding side; (θ) tenderness along the course of the jugular in the neck, and perhaps the cord-like feeling of the infected vein; (γ) beginning neuroretinitis—a majority of these symptoms should be present.

2. The indications for ligation after exposing the sinus and recognizing it, but before opening it: (α) The presence of a clot extending well down into the bulb, and disintegrated in its lower portion (as indicated by aspirator), associated with distinct pyemic symptoms, although metastases are absent; (β) the display by the sinus of respiratory movements would render probable the admission of aerial embolism to the heart unless the vein were first tied.

3. Indications for ligation after exposing and opening the sinus: (α) The presence of a large thrombus, extending down into the bulb, and having undergone purulent liquefaction in the deep bulbous portion, which may not have been diagnosed until the sinus was extensively opened; curetting deeply in the neck under such conditions is fraught with imminent risk to the patient unless the vein is tied. (β) Inability to reestablish the circulation from below, whether the clot has or has not disintegrated, and whether or not there has been tenderness in the neck. (γ) Inability to reestablish the circulation from either direction has aroused some discussion as to the advisability of ligating both jugulars.

In cases of ear disease of doubtful origin, and where the symptoms complained of are mainly of a subjective character, it is a good and wise rule to carefully analyze the urine.

Dowling has found that certain cases, accompanied by such symptoms as tinnitus, dull aching pain about the mastoid process, deafness, slight irregularity of gait, etc., are associated with renal changes. He believes that the retention of certain products in the blood produces a toxic irritation of the auditory filaments, and possibly causes an albuminous degeneration similar to that occurring in retinitis albuminurica.

From a summary of fifty-six cases (fifty-three from literature and three cases of his own), Morf has come to the conclusion that the aural changes due to nephritis may be divided into two main groups. The first group includes those cases where definite pathological processes in the ear—macroscopic, microscopic, or those revealed by functional examination—are found; the second group, those cases where no tissue changes can be made out to account for the functional disturbance. Middle-ear affections are present in three forms—inflammatory, inflammatory-hemorrhagic, and hemorrhagic.

Rosenstein was the first to suggest the possibility of an edema of the auditory tracts causing disturbances of hearing in nephritic patients. The author is inclined to regard the anesthesia of the auditory nerve and the tinnitus as symptoms of chronic uremia confirmed by the slight diminution of vision without ocular changes, which could be regarded as a uremic amblyopia. The usual auditory symptoms are subjective noises and a loss of hearing. Deafness may vary in degree and duration. The diagnosis of a nephritic affection of the ear is confirmed when, in addition to the nephritis, a direct connection of the latter with the aural disturbance is ascertained. Hemorrhages are always ominous, as they are usually soon followed by death. In purulent middle-ear disease a nephritic basis is a bad prognostic omen.

CAUSES AND TREATMENT OF BALDNESS.

A monograph upon this important subject by Gessner has been extracted by Vogt (La France Médicale et Paris Médical, No. 22, 1899). Chronic seborrhoea, he states, is not of such serious prognostic importance as is generally supposed, providing that timely treatment is employed. This prophylactic treatment consists mainly in the thorough application of soap; tincture of soap, with the addition of a little lavender, is especially recommended. This is rubbed in, after which the hair is washed with very hot water, which in turn is followed by cold water.

In case the skin is irritable or inflamed, or if there is eczema, the following ointment is used:

Ichthyol, 0.5;
Oxide of zinc,
Starch powder, of each 2.5;
Vaseline, 20.0.

On first beginning this treatment after baldness has commenced, many hairs will come out, but these are all irretrievably lost and simply hang in their follicles. They should be removed to make room for others. This treatment is employed once or twice a
week, and to avoid the removal of too much fat, it is followed by an application of oil. After thoroughly cleansing the scalp, as a means of treating seborrhea, the following ointment should be used:

Precipitated sulphur, 1 to 2;
Pure resorcin, .5 to 1;
Salicylic acid, .25 to 1;
Tincture of benzoin, .5;
Vaseline, 20.

This ointment is applied directly to the scalp while the hair is being separated by a comb and is rubbed in. This treatment is usually applied in the evening, after which the head is covered by a nightcap. As a substitute for the ointment the following may be employed:

Pure resorcin, 3 to 6;
Hydrate of chloral,
Tannic acid, of each 0 to 10;
Tincture of benzoin, 2 to 4;
Castor oil, 5 to 10;
Alcohol, 200.

When baldness already exists the scalp must be vigorously stimulated; for instance, by applying every evening with a stiff brush an ointment containing five to ten per cent of chrysarobin; the scalp is then covered with a cap. At the same time faradization with a brush is practiced daily from five to ten minutes.

A CONTRIBUTION TO THE CRÉDÉ SILVER METHOD OF WOUND TREATMENT.

Meyer (Southern Practitioner, June, 1899; abstracted from the Deutsche Militairärztliche Zeitschrift, xxviii, No. 1, Berlin, January, 1899) states that the conclusions may be drawn from a series of reported cases may be stated as follows:

The course of a wound under the silver treatment is in general similar to that under the usual aseptic and antiseptic procedures. But silver possesses two important advantages. Rapid and reliable healing can be obtained without asepticism and with less rigorous antiseptic measures, and thus with simpler means and less trouble. Hence it is especially suitable for the sick-bays of ships, for use in the field, and for hospitals where the facilities for aseptic wound treatment are deficient, and suppurring affections and fresh wounds have to be handled in the same rooms or very hurriedly, or with inexperienced assistants. The author states that as far as his material permits him to judge, he has found Crédé's statements to be correct, and considers his method an efficacious and handy one.

The second advantage is the marked tendency of the method to effect the localization of inflammatory processes, as Crédé claims. In most cases the inflammation of the tissues surrounding the lesions subsided in the shortest time; and even when it progressed along the lymphatics a general infection was prevented.

Poisoning by the metal, or any special pain from its use, was not noticed; eczemas did not occur. The course of healing was noticeably shortened, and primary union took about the same time as with aseptic treatment. Necrotic tissue, when present, was cast off with a non-irritating suppuration before actual union began. The cases of general infections and of burns were too few to permit of a definite judgment; but a favorable reaction of the system to the incisions was readily recognizable. Granulations under the citrate were almost always remarkable for their vivid color and vigorous growth.

The abundant serous secretion from the tissues was apparently a disadvantage in the cases where a primary union was desired; but whether this was dependent upon the citrate itself or upon other circumstances the author cannot decide.

The cost of the silver treatment Meyer did not find to exceed that of other methods. The citrate of silver is dearer than iodoform, but it is used in very much smaller quantity, as a very thinly dusted-on covering. The silver gauze is too expensive for universal use, but the author believes that common gauze with the citrate will do just as well. The price of the ointment is of no importance, on account of the small quantities that are employed.

The following is the method which Meyer now employs for ambulant patients, in view of the very reliable anti-inflammatory and localizing properties of the Crédé silver preparations: Injuries and inflammatory processes are treated with silver until all traces of inflammation have disappeared, and until healing by adhesion and granulation formation has begun in the depths of the wound. Cicatrization may be promoted by cauterization and salves. Operative wounds in which primary union is not absolutely necessary are treated with silver if it does not appear that the abundant serous secretion interferes with the healing. For febrile symptoms he employs the salve by inunction; more rarely, he administers the silver internally.

In conclusion the author states that the silver treatment, while not equal to the asep-
tic treatment of wounds, is reliable where the latter cannot be carried out, as in non-aseptic hospital operating-rooms, dressing-rooms, in sick-bays, in private practice, and especially in the field. In the latter case the removal of the first dressing need not be a matter of such anxiety as it now is, even if it is soaked with secretion from the wound; for it is proven that the bacteria cannot develop in secretion impregnated with silver.

The author's experience leads him to place the fullest reliance upon the silver treatment of wounds, and he can recommend it in every respect in the most emphatic manner.

COMPLETE REMOVAL OF BLADDER, PROSTATE, SEMINAL VESICLES, ENTIRE URETHRA AND PENIS, SCROTUM AND ITS CONTENTS, FOR TUMOR OF THE BLADDER.

Dr. Hogge (Annales d. Med. d. Org. Génito-Urin, p. 838, 1898) presented the specimen and history of the patient before the Soc. Méd., Chir. de Liège, December 2, 1897. The specimen consisted of all the organs enumerated in the title, and was an enormous epitheliomatous papilloma of two years' growth. Age of patient and time of operation not given.

The operation was performed January 3, by Professor Winiwarter, assisted by the author, and was done by several stages.

First Stage.—Lithotomy position; the bulb, membranous urethra, and prostate exposed and separated from rectum and the wound tamponed.

Second Stage.—Symphysis exposed; detachment of the suspensory ligament of the penis; insertions of the corpora cavernosa; symphyseotomy. Hemorrhage from the plexus of Santorini stopped by tamponade. Pubes separated by abduction of flexed thighs, which at this point caused rupture of bladder and hernia.

Third Stage.—Separation of peritoneum from bladder and of the prostate from rectum, with the fingers, the patient being placed in the Trendelenburg posture.

Fourth Stage.—Section of lateral attachments of bladder and urethra, ligation of ureters, patient being placed again in lithotomy position.

Fifth Stage.—Implantation of ureters into the anterolateral wall of the rectum, two catheters cut square being introduced into rectum into the ureters, and ureters sutured into rectum.

Sixth and Seventh Stages.—Closure of symphysis with silver wire, the abdominal and perineal wounds with silk sutures, and a Mikulicz tampon placed behind the pubes. Recovery of patient.

The catheters were removed from the rectum in forty-eight hours, and urine passed by rectum. By February 10 pains had disappeared; condition of patient excellent; gain in weight. There was left one fistula, from anterior wall of rectum, from which there was some escape of feces and urine. Patient went to stool only once a day; most of the urine passed by the fistula, and caused itching and discomfort in the anal region; otherwise good recovery.

ANESTHETIZATION OF THE SPINAL CORD BY COCAINE INJECTIONS.

Bier (quoted in Münchener Medizinische Wochenschrift, No. 21, 1899) has conducted a remarkable research, having for its object the production of anesthesia in large sections of the body by means of cocaizing sections of the spinal cord. After having employed Quincke lumbar puncture, a very small quantity of cocaine was injected into the subdural space—from one-twelfth to one-sixth of a grain. Following this injection operations such as resection of the ankle and knee-joints, sequestrotomy of the tibia, resection of the tuber ischii, and resection in complicated fractures of the femur could be employed without the patient feeling the faintest sensation of pain. For one or two days after these injections patients complain of cephalalgia, vomiting, and general misery.

With a scientific ardor truly Teutonic, Bier practiced these injections upon himself and upon one of his colleagues, Hildebrand by name. In five to eight minutes after the injection the legs were entirely anesthetic; under one-twelfth of a grain of cocaine this anesthesia lasted forty-five minutes; it then gradually passed away. The after-effects were extremely severe in both cases, Bier being kept to his bed for several days.

SURGERY OF THE HEART.

Podrez (Revue de Chirurgie, No. 5, 1899) quotes Jamain statistics to the effect that of 121 cases of wound of the heart and of the large blood-vessels, but a small number resulted in immediate death. Fischer finds, in a study of 452 cases, that the right ventricle is most frequently wounded; he gives the
mortality of non-penetrating wounds of the heart at ninety per cent. Ollier and Sanson have reported twenty-nine cases of penetrating wounds of the heart in which the patients survived more than two days.

Wounds of the auricles and the coronary arteries are more rapidly fatal than wounds of the ventricles; the disposition of the muscular fibers contributes toward the arrest of hemorrhage, so that the wound possibly can close itself completely, and thus entirely stop the loss of blood.

Jamaín found in thirty-five wounds of the right ventricle that the patients lived from four hours to twenty-five days; that of a number of lesions of the left ventricle, two patients lived a half-hour, one six months; that in five cases in which both ventricles were wounded the period of life varied from an hour to nine months; that in seven cases in which the right auricle was wounded the patients lived from seven hours to twenty days; of two patients wounded in the left auricle the period of life was one and two days respectively.

Syncopé often plays an important part in arresting hemorrhage, but it may itself be fatal, and on reaction the hemorrhage is likely to recur.

The situation of the external opening is of great importance in making a diagnosis of wound of the heart. Pain is a very common symptom, together with shock, free bleeding, embarrassed respiration, marked irregularity in the pulse, and augmentation of cardiac dulness. To these symptoms are often added trembling, convulsions, vomiting, and even temporary hemiplegia. Shock is a secondary effect of heart wound, and should not be treated until the opening in the heart itself is closed. Hemorrhage is much more likely to be free from wound of the large vessels and of the auricles and of wounds of the ventricles. This bleeding is not the principal cause of death.

Wounds of the coronary arteries are always fatal, and usually immediately so after traumatism; the cause of death is not bleeding; but cardiac arrest because of insufficient supply of blood to the heart muscle.

Respiratory disturbances are usually early symptoms of heart wound, and there is a feeling of suffocation which may go on to apnea. The heart itself becomes rapid, feeble, and irregular, and often there is heard on auscultation a blowing sound, not unlike that of aneurism. This cardiac irregularity may persist for a long time; indeed, there is reason to believe that complete recovery from it is never accomplished.

The condition of the pericardium, especially the amount of distention in it, is extremely important in its influence upon the activity of the heart. When this serous pouch is distended the heart acts very badly, especially if the distention is rapid in development. The prognosis of wounds of the pericardium is extremely grave, according to Erichsen, because of the disturbance in the heart's action, which may result in death a long time after the wound.

When there has been inflicted a penetrating wound of the heart a spontaneous arrest of hemorrhage cannot take place, unless the opening is a very small one of the left ventricle. Such wounds have at times closed spontaneously, and apparently permanently, by a dense cicatricial tissue. Hence it follows that whenever a penetrating wound of the pericardium is followed by the symptoms of bleeding or compression of the heart, a large incision should be made in the cardiac region. After having made a provisional resection of the upper part of the thorax and explored the heart and the cavity of the pericardium, the wound is either sutured or tamponed, according to its nature.

It often happens that death follows so quickly that intervention is impossible. Even when this is not the case, the technical difficulties of the operation are considerable. It has been abundantly demonstrated that there is an extreme inconstancy in the limits of the region within which the surgeon is enabled to incise the thorax and the pericardium without wounding the pleura. A direct penetration of the pericardium is only possible to the left of the lower extremity of the sternum, and about the position of the articulations of the sternum with the fifth, sixth, and seventh costal cartilages, not far from the point where the cartilages become continuous with the bony ribs. The opening confined to this region does not give sufficient room for intrapericardial manipulations. The only satisfactory method consists in a large opening of the region by a flap incision; the best flap is that which includes nearly all the left half of the lower extremity of the sternum, and the third, fourth, fifth, and sixth costal cartilages; the latter may be sectioned at the position of the costocartilaginous articulation.

The incision begins an inch and a half from the left border of the sternum and the second intercostal space, is carried to the
midsternal line, then almost vertically downward, following the middle line of this bone as far as the seventh sternocostal articulation. At this point it curves outward, following obliquely the seventh cartilage. After having penetrated into the mediastinal cavity at the level of the seventh costosternal articulation, Volkman's resection scissors or other convenient cutting instrument is employed, cutting directly upward through the sternum in the line of the skin incision to the second intercostal space; here the bone is cut transversely to the left. By care the periosteum of the lower surface of the sternum may be separated before the bone is divided, thus avoiding wounding the pleura, especially when before lifting up the flap the pleural cul-de-sac is stripped outward. Even though the pleura is opened this does not constitute a serious complication.

The author cites a case of cardiac surgery. A girl, sixteen years old, was shot in the stomach and chest with a revolver; this was followed by deep syncope, from which recovery was very gradual. Two hours later she was brought to the hospital exhibiting profound shock; the pulse was scarcely perceptible, respiration was irregular and superficial, the heart-beat could not be heard. Percussion showed increased dulness to the right. The patient complained principally of thoracic pain and dyspnea. The wound was placed in the region of the fifth costosternal articulation; it passed obliquely upward to the left, and was penetrating. The patient showed some reaction after exploration of the wound, but two days later the heart dulness increased, and the other symptoms of hemorrhage into the pericardium appeared. The pulse diminished in intensity, and a sense of suffocation and nervous depression developed.

The patient was etherized and a grooved director was introduced to a depth of two inches, evacuating a turbid and yellowish fluid; the end of the sound was in direct contact with the heart. The wound track was enlarged and drained. About half a glassful of liquid was evacuated. As the pericardium was relieved of pressure the general condition improved.

The next day the symptoms recurred with increasing violence. A flap was raised, and the entire heart was exposed, together with the large vessels. The pericardium was irrigated with boric acid solution and the wound was looked for. After having stripped off some false membrane a longitudinal whitish opening was found in the surface of the right ventricle, about an inch from the apex of the heart. The introduction of a grooved director showed that this opening was closed rather by muscular fibers than by cicatricial tissue. By means of a needle the ventricle was explored, in the effort to find the foreign body. More than ten punctures were made, but the bullet could not be found. A manual examination of the pericardium was then made, and finally the heart was seized between the two hands, an effort being made to detect the foreign body by manual palpation. Neither the punctures of the needle nor the lifting of the heart from the pericardial cavity and its firm compression between the two hands arrested its movement. This organ continued to contract irregularly but sufficiently. For a week the pericardial cavity secreted an abundant purulent liquid. About the end of the third week the secretion had almost entirely disappeared. The packing was then replaced by a drain.

Later, by means of the fluoroscope, the foreign body was seen above the upper border of the fifth rib, an inch from the left border of the sternum, and about the same distance from the left nipple. This foreign body moved in correspondence with the rhythmic contractions of the heart, showing that it was placed within this organ. The patient five months after operation was well, and was still carrying the foreign body in the heart substance.

FOREIGN BODIES IN THE PHARYNX AND ESOPHAGUS.

Jones (The Lancet, May 6, 1899) states that from a study of his own cases of esophagotomy and a perusal of general results, he would submit: (1) That bodies which have lain for some time and given rise to symptoms of obstruction, irritation, or dyspnea should be operated upon without delay; (2) that forcible attempts at extraction by the mouth are to be condemned; (3) that sharp or irregular impacted bodies specially demand esophagotomy; (4) that in certain cases gastrotomy is indicated, and in some a combination of gastrotomy and esophagotomy; (5) that where the wound in the esophagus is jagged or its walls inflamed no stitches should be used; (6) that the routine practice where the esophageal wound is clean cut is to stitch it up with a continuous suture, care being taken as in the case of the intestine not to pierce the mucous coat; (7) that
only in very exceptional cases where no danger of suppuration and infection exists should the external wound be closed; and (8) that liquid food may be given by the mouth in about twenty-four hours after operation.

THE USE OF HOT STEAM IN DERMATOLOGY.

LIEBERSOHN (quoted in Münchener Medizinische Wochenschrift, No. 21, 1899) has obtained excellent results by the use of hot steam long continued in a number of chronic skin diseases. He states this measure is specially indicated in circumscribed cases of chronic eczema, particularly of the face, and in suppurative forms; in acne, in non-parasitic sycoysis, in leg ulcer, rosacea, lupus vulgaris, veneral ulcers, and erythematous lupus. It is contraindicated in acute forms of eczema, in the diffused and varicose manifestations of this disease, in psoriasis, favus, and herpes tonsurans.

Of twenty-two cases of chronic eczema thus treated only one was uncured. The results were especially brilliant in sycoysis, leg ulcer, and acne. All such cases thus treated were cured.

A CASE OF ACUTE CARCINOMA OF THE BREAST.

J. B. Davey (Treatment, May 25, 1899; quoted from Middlesex Hospital Journal, February, 1899) reports the following unusual case: The patient, a married woman aged twenty-nine, was admitted, under Mr. Pearce Gould, on October 8, 1898, with the following history: Ten months ago she gave birth to her fourth child, which she continued to suckle until a week ago. Seven weeks ago the baby refused to take the left breast, although at that time the patient did not notice anything the matter with it. Shortly after that, however, the patient found that her left breast was “hard and lumpy.” She continued to suckle the baby at the right breast until a week ago, when it was weaned. The left breast got much larger after the baby refused it, but recently it had not increased. For three weeks the skin over the left breast had been reddened, and during this time she had suffered much pain in the lower part of her spine. The patient stated that during the last eight weeks she had lost much flesh. There had been no discharge from the nipple. Since her confinement the patient had not menstruated.

On examination the left breast was seen to be prominent, especially internal to and slightly above the nipple; the skin covering it was discolored and blotchy, varying in color from red to brown, and indented by numerous small dimples. The nipple was retracted; there was no discharge from it. The whole breast was felt to be converted into a firm mass, and around it there were numerous small, hard, bright crimson nodules in the skin, and some also in the subcutaneous tissue. A group of these passed backwards almost to the posterior fold of the axilla; there were several on the upper and inner aspect of the breast. The skin was firmly bound down to the swelling, which was partly fixed to the pectoral muscle. The swelling was fairly well defined and not tender, except on very firm pressure. A chain of enlarged hard glands was traceable from the breast to the apex of the axilla. No glands were felt above the clavicle.

The right breast was large and its nipple well formed. In its upper part several very hard, small, rounded nodules were felt; these were not adherent to the skin, and no enlarged glands could be felt in the right axilla.

From the date of admission to the hospital to the date of her death, which took place on November 4, barely four weeks later, the condition of the patient became rapidly worse.

The condition revealed by the post-mortem examination was a remarkable one. Although the disease was of only eleven weeks’ known duration, the secondary growths were exceedingly numerous and somewhat unusual in their distribution. They clearly explained the symptoms exhibited during life. The lungs and pleura have been found to be most frequently affected; but in the case under consideration, although both pleura were extensively affected, no growth was found in the substance of the lung itself. The liver is most frequently affected after the lungs and pleura, and in this case was thickly studded with cancerous nodules. Next to the liver, the kidneys, bronchial glands, opposite breast, peritoneum and mesenteric glands, heart, and pericardium are most often affected; but in this case all these organs, excepting the opposite breast, were found to be free from cancerous growth.

Mr. Gould recently removed both breasts simultaneously from a patient aged forty-eight, and both breasts were the seat of cancerous growth. A tumour had first been noticed in the left breast four and a half
years previous to operation. The patient made a good recovery. In the case under consideration the second breast was evidently early affected, and it is interesting to note that although on admission to the hospital the second breast was evidently affected, the child had taken that breast until a week before, when it was weaned, so that the disease had probably reached considerable development in the left breast before the child refused to take it.

ABLECTION OF THE GASSERIAN GANGLION.

COELHE (Revue de Chirurgie, No. 5, 1899) operated upon a man who, for the relief of neuralgia affecting all three branches of the trigeminal nerve, had been subjected to tooth extraction, sea baths, electricity, cauterization, and all the known methods of conservative treatment. In 1894 a surgeon divided the infra-orbital nerve; the next year another surgeon divided the superior maxillary. These operations were futile.

In 1898 Coelhe resected the Gasserian ganglion, together with the protuberance. The eye was first occluded by sutures, after disinfection of the conjunctival cul-de-sac; a curved incision was then made, beginning behind, a little below the external orbital angle, carried upward and backward for two inches, then curved downward to a point just in front of the tragus. This incision was carried down to the bone, the divided blood-vessels being ligated; the zygoma was mobilized by two incisions in the line of the skin cut; this flap was turned downward, together with the periosteum, which was stripped off the skull by means of trephine and forceps. The opening of the skull was made about an inch and a half in its anteroposterior dimension, an inch in vertical measurement. The dura mater was then separated by a strong polished elevator about an inch and a half long and an inch wide, slightly angled at its end. By means of this instrument the middle meningeal artery and the superior and inferior maxillary nerves were exposed. In separating adhesions there was a free hemorrhage, which was only checked by packing. The operation lasted forty-five minutes.

Three days later the packing was removed, and the superior and inferior maxillary nerves were divided by a blunt-ended tenotome quite near the ganglion. For the isolation of the ganglion a spatula was used about three-fifths of an inch long and one-fifth of an inch wide, with a slight anteroposterior curvature; it was carried backward and upward, avoiding the cavernous sinus, and passing above the ganglion; when the latter was freed it was seized with hemostatic forceps and torn away by a movement of traction. The separation of the upper surface of the ganglion has often been considered impracticable; the author found, however, that it was extremely easy. Seizing successively each of the maxillary nerves in the cranial cavity, they were drawn out and cut as short as possible. This second operation occupied twenty minutes.

A microscopic examination of the ganglion showed that it was the seat of marked degeneration. Five days after operation the eye was opened and found to be normal. Next day the cornea was slightly opaque. By lavage a thin superficial layer was detached, leaving an absolutely transparent surface. Continuing with compresses and aseptic treatment, the opacity recurred. At the end of a month it was, however, entirely clear, with the exception of one spot. It was found when the eyelids were kept closed that the cornea remained clear; when the eyelids were allowed to remain open, however, because of the insensibility resulting from operation, the cornea was not protected from mechanical irritation. The neuralgia was entirely cured.

Coelhe states that the ablation of the Gasserian ganglion should be the measure last attempted in the treatment of trigeminal neuralgia, since it is dangerous, principally because of the possibility of wounding the internal carotid artery. Lesions of the cavernous sinus and of the middle meningeal, though not as dangerous, since in general the bleeding can be controlled, weaken the patient and prolong or adjourn the operation.

Cerebral compression, shock, and secondary infection have been causes of death. The operation should consist in tearing away the trigeminal at the protuberance, as a means of avoiding recurrence, since thus it is certain that the entire ganglion is removed, whilst the same certainty does not exist when the isolated extirpation of the ganglion is attempted.

PRACTICAL POINTS IN THE MANAGEMENT OF SKIN DISEASES IN CHILDREN.

BULKLEY (New England Medical Monthly and the Prescription, May, 1899) says it is well always to bear in mind the very abundant nerve supply of the skin and the very
tender and delicate character of the skin in early life, as indeed at every age. Zinc oint-
ment has been a boon to eczema, because it affords a simple and non-irritating dressing in most cases, and the profession has done well to employ it so largely. But it is a relatively inert and ineffectual remedy when used alone, although with certain additions it often proves of the greatest service. Ich-thylol, two to ten per cent, and salicylic acid powdered, two to five per cent, in zinc oint-
ment, are often most valuable in these cases. The old tar and zinc ointment is as follows:

\* Unguent. picis, 3 ij;
\* Zinci oxidii, 3 j;
\* Unguent. aquae roseae, 3 vj.

It often affords the very best dressing possi-
ble, and, if correctly and faithfully applied, remains still one of the best applications for eczema.

A word in regard to the method of making applications of ointment, especially to chil-
dren, for we may be sure that they will not be employed exactly in the right manner, unless special directions are given. It is better to expect that patients and attendants know nothing rightly in regard to the details of treatment, and therefore to give very full and explicit directions in regard to methods and mode of treatment.

To be effective an ointment should be kept in very close and constant contact with the part, and the common method of smearing the surface and then placing linen or other covering upon it seldom suffices for the proper treatment of eczematous surfaces, where the disease is at all severe. The author states he has long advised that the ointment be thickly spread upon the woolly side of lint, cut to fit the diseased surface, and that it then be bound firmly on with gauze bandage. It is surprising to see how much better a suitable ointment works when thus correctly applied than when simply rubbed on the sur-
face.

On the face it is not often desirable to thus bind it on, but it should be reapplied as often as it is at all disturbed, even many times daily.

The author mentions a device for restraining an infant from scratching and tearing itself, which he does not think is as widely known and employed as it should be. This consists in the use of a small pillow-case, with an opening at the closed end, sufficient to admit the head being passed through it. This is drawn down upon the baby, and secured from being raised by means of a safety-pin between the legs. A few more safety-pins suffice to secure the arms in place, at the sides, thus making it impossible for the child to reach its face, or even the other hand. It may seem a little barbarous in de-
scription, but after employing this method in suitable cases for many years he has found it to be of the greatest service; the little pa-
tient becomes accustomed to it very readily, and does not seem to dislike it more than many of the restraints of childhood; many parents who have used it heartily approve of the method.

In regard to the treatment of infantile syphilis little need be said, for the simple means used years ago remains to-day the best method of combating the disease; and that is by means of mercurial ointment, diluted one-half with cold cream, rubbed into the body and kept applied on the flannel band. There is little danger of the child absorbing too much; a half-drachm may be used night and morning. Iron and appro-
priate tonics are required later in the disease, and in the very late forms the syrup of the iodide of iron, even in heroic doses, proves most serviceable.

The question as to the cure of ringworm of the scalp is always a serious one; that is, just when the patient is perfectly well and not liable to communicate it to other chil-
dren. This is often a very difficult question to decide, even to one familiar with the dis-
ease.

Long after the diseased patch has repro-
duced good hair of some length there may be small stubs of broken and diseased hairs, or worse still minute black spots, representing the ends of hairs broken off at the mouth of the follicle; these are yet filled with the spores of the vegetable parasite, and are capable not only of autoinoculation and the production of active disease in the patient, but also of inoculating others.

Cases should never, therefore, be pronounced cured and be allowed to mingle freely with other children until the physician is assured from personal observation that such diseased remnants of hairs are not present. Now this is often a very difficult matter to determine, and the proper examination of the scalp may take many minutes, some writ-
ers say half an hour. The hair should be carefully turned back with the blade of a forceps, and all the surface searched with the aid of a lens. It is often necessary to leave a child without treatment for a while, in order that this may be properly done; then.
if there are any suspicious hairs or stumps, these should be extracted and examined microscopically. A case should really not be discharged as cured unless a second or even a third such examination has failed to reveal the presence of the parasite.

Acute urticaria, nettle-rash, or hives, when it bursts out, with its characteristic wheals, from some indiscretion in diet, is easily recognized and commonly yields readily to appropriate treatment. But in certain cases there is only the indistinct history of itching, with restlessness at night, and the wheals may be few and far between, and the condition may often be prolonged for a very considerable period and prove very rebellious to treatment. It must never be forgotten that articles of food, such as oatmeal, which are perfectly healthful for many or most persons, will, from an idiosyncrasy, prove very irritating to certain individuals.

The local treatment which is commonly so promptly effective in impetigo contagiosa consists simply in the official white precipitate ointment, diluted with three times the amount of cold cream. It is often surprising how rapidly even quite an extensive eruption of this kind will disappear under the thorough and continuous application of this ointment.

**ARTERIOVENOUS ANEURISM OF THE FEMORAL VESSELS SUCCESSFULLY TREATED BY EXTRIPATION OF THE SAC.**

MURRAY (The Lancet, June 3, 1899) treated by radical operation a case of arteriovenous aneurism of the femoral vessels of eight years' standing. The patient wounded himself with a penknife and bled profusely. Under a compress this wound healed, but distinct pulsation was noted. A tumor formed, which gradually increased in size. Yet, in spite of this, the man was extremely active, running races and riding long distances on his bicycle. Shortly before operation the tumor grew rapidly, and because of increased pulsation and thrill in the limb sleep was interfered with; moreover, there was much aching and numbness in the leg. The tumor was as large as the fist, lying just under the skin, covering the site of Hunter's canal. One tourniquet was placed round the leg, immediately below the knee; the second one round the thigh as high up as possible. An incision eight inches long was then made over the course of the femoral vessels, the sac exposed, dissected free of the muscles to which it was adherent, and the artery and vein, both much dilated but otherwise apparently healthy, were tied three-fourths of an inch above their communication with the sac with catgut ligatures. About one-fourth of an inch below the point of communication the artery was smaller than natural, the vein larger. They were both secured with catgut ligatures. The sac was then dissected out and was, together with the attached portions of the artery and the vein, removed. The recovery was uneventful.

Dr. Curtis has collected details of twenty cases of varicose aneurism treated by extirpation of the sac, with nineteen cures and only one death, the latter due to sepsis. Among these twenty cases there were six femoral, three popliteal, and three axillary varicose aneurisms, all of which were permanently cured.

Keen, because of a very rapid advancing varicose aneurism in the case of a boy, aged fifteen years, tied the common carotid and internal jugular vein above and below, and attempted to extirpate the sac. Though the latter part of this operation was not practicable, the boy was cured. Keen agrees with Curtis that cases of arteriovenous aneurism of the common carotid and internal jugular seldom require surgical treatment.

Page has had under observation for eight years a patient who has an aneurismal varix of the common carotid and internal jugular vein, but no aneurism has developed, though the vein is very much dilated.

**ANEURISM OF THE SUBCLAVIAN ARTERY TREATED BY PROXIMAL LIGATION, FOLLOWED AFTER AN INTERVAL BY REMOVAL OF THE SAC.**

ALLINGHAM (The Lancet, June 3, 1899) had brought to him a sailor, twenty-five years old, who for twelve months had been suffering from a swelling above the right clavicle, which gradually increased in size. This was accompanied by pain, at first intermittent, lately continuous, situated in the right upper extremity. This tumor exhibited all the characteristics of aneurism. A V-shaped incision was made, one arm of which ran down the anterior border of the sternomastoid muscle, the other arm along the clavicle; the sternomastoid muscle was divided; the first part of the subclavian artery was exposed, and a kangaroo tendon passed round the vessel immediately external to the origin of the
vertebral artery and just at the inner border of the scalenus anticus. Pulsation persisted, and the aneurism continued to grow. Thirty-eight days after the first operation the whole length of the clavicle was exposed by a transverse incision; a further vertical incision was made to give added room. The greater part of the clavicle was resected, leaving only the two extremities. Careful dissection revealed the aneurism springing from the upper and anterior aspect of the vessel in its third portion. The tissues surrounding the aneurism were dissected off the sac. The axillary artery was ligatured with silk and divided on the distal side of the tumor. This procedure allowed the aneurism to be freed from the first rib and turned upwards, and so to bring into view the second part of the subclavian artery on the proximal side of the aneurism. This part of the vein was ligatured with silk and the aneurism was cut away. The subclavian vein was torn, but this opening was closed by lateral ligature. The operation occupied two hours. The axillary artery, as far as it was exposed in the wound, was found to be obliterated. A month later pulsation was present in the brachial artery and also in the radial at the wrist.

FIBROUS STRicture OF THE RECTUM.

Horrocks (British Medical Journal, June 3, 1899) states that fibrous stricture of the rectum, unaccompanied by ulceration, is not a common affection, and is difficult to treat satisfactorily. It occurs more commonly in women than in men. The situation of the stricture especially considered is from one to two inches from the anal margin, where the levator ani slings the rectum. The stricture is usually a narrow one, but in some cases the strictured part is an inch or more in depth. Such strictures have been attributed to the fibrous thickening in the sheath of the levator ani, caused by long-continued reflex spasm of that muscle. The originating irritation is usually some piles or an ulcer about the anus. Dr. Reider attributes it to syphilitic infection of the pudendum, which sets up endophlebitis and periphlebitis of the rectal veins, which carry away the blood from the pudendum.

The usual treatment by passing bougies is very painful, and affords only temporary relief. Forcible dilatation is a dangerous and unscientific method. It is dangerous because the stricture yields at its weakest part, which may lead to laceration and infection of the peritoneum. It is unscientific, as the tear when healed leaves the patient in much the same condition as before the operation. The method here advocated is so simple, and in two cases was so satisfactory, that there seems no reason why it should not come into general use. It consists of a vertical division at the part most removed from the peritoneum. The vertical is converted into a transverse slit, and the margins stitched together. To do this the stricture must be within reach, and it is an advantage if the mucous membrane above the strictured part is loose and healthy.

NEPHROTOMY IN A CASE OF SURGICAL ANURIA.

Nélaton (La France Médicale et Paris Medical, No. 22, 1899) performed a celiotomy for the relief of what was supposed to be a cyst of the ovary. This cyst was, however, found to be postperitoneal, and was in reality a hydronephrosis. The kidney substance was practically completely atrophied; therefore the tumor was removed and the abdomen closed. On the eighth day the patient suffered with severe pains in the right flank; it was the left kidney which had been taken away. The attack was so like kidney colic that morphine was given. On the evening of that day only a few drops of blood-stained urine was passed. Uretral catheterization was practiced, but without effect. Therefore, as the patient had suffered from anuria for forty-eight hours, a palliative nephrotomy was practiced. This showed nothing abnor mal. A tube was placed in the pelvis of the kidney, and in a few hours the urine began to flow through it. Seven days later some of the urine appeared in the bladder. For several weeks the secretion was extremely irregular, varying from an ounce to four pints a day. After that it became fully reestablished.

SUTURE OF THE HEART.

Weber (Centralblatt für Chirurgie, No. 27, 1899), on the basis of an experimental investigation, states that before a heart wound can be quickly and safely closed by suture, the organ must be exposed by the feest possible parietal opening. Compression of the heart, in order to make the operation a bloodless one, is not practicable in dogs because it often causes death. It is worthy of note that of ten dogs the hearts of which had been wounded after the organs were ex-
posed, three lived; of nine dogs operated on for heart wounds inflicted through the parietes, two lived.

The incision suggested by Weber, as the one most suited to allow of free access to the heart, is one beginning to the left of the sternum, just above the insertion of the fourth costal cartilage. The cut is carried in the form of an ellipse, through the skin and muscle down to the bone, transversely across the sternum to the upper border of the fourth left costal cartilage, two fingers' breadth beyond the left sternal border, and downward over the fourth, fifth, sixth, and seventh ribs; finally inward to the base of the xiphoïd process, terminating at the right sternal border. The sternum is sawn through in the line of this incision; then after cutting the intercostal muscles in the third interspace, taking care to avoid the internal mammary artery, the fourth, fifth, sixth, and seventh costal cartilages are cut through, and the flap thus formed is folded over toward the right side, the base of the xiphoïd process being cut through before this is accomplished.

Riedel, commenting upon this communication, reported that a patient operated upon by him for heart wound two years before was still living and well. He stated that in case of pericardial effusion the heart is not forced away from the chest wall, as is commonly taught, but lies close to it.

Eichel contradicts this last assertion on the basis of a case which came under his own care. The patient was shot with a pistol ball and developed a pericarditis, which made operation necessary. The sternum was resected from the fourth, fifth, and sixth ribs, together with portions of the rib cartilages. Over a pint of pus was evacuated from the pericardial sac before the heart could be felt by the finger.

STERILIZATION OF THE SKIN.

Senger (Centralblatt für Chirurgie, No. 27, 1899), investigating the value of alcohol as a disinfectant for the hands, finds that absolute alcohol will not destroy staphylococcus aureus in twenty minutes. The disinfecting power of this agent increases, however, as this drug is diluted down to fifty or forty per cent. After this the germicidal effect of the drug rapidly disappears. As a result of his experience, he states that a fifty- or forty-per-cent solution of alcohol is a sure bactericide for the staphylococcus. If a mixture of alcohol and carbolic acid is employed the result is less satisfactory than when alcohol alone is used, since a chemical combination results, with the formation of a kind of ether. A mixture of five-per-cent carbolic solution with ten-, twenty-, or thirty-per-cent absolutely pure alcohol is entirely inefficacious.

For three years Senger has employed a method of disinfection of the skin based upon his chemical studies. Two agents were employed which had the power of destroying the cocci, and which entered into a chemical combination which in itself is bactericidal. He employs first a two- and five-per-cent warm solution of hydrochloric acid for two minutes, then a half- to two-per-cent warm solution of potassium permanganate for one minute. The resultant brown discoloration of the skin may be removed in a few seconds by sulphurous acid. The action of the hydrochloric acid on the potassium permanganate causes among other things the development of free chlorine. Oxygen and sulphuric acid are also formed.

According to Krönig and Paul, a one-per-cent solution of hydrochloric acid with one-per-cent solution of potassium permanganate acts far more powerfully upon anthrax bacilli than a five-per-cent solution of sublimate. After bacteriological investigation the author has proven that a one-per-cent solution of hydrochloric acid at about the body temperature is an extremely powerful bactericide. Sulphurous acid and potassium permanganate are weaker. By means of this method he has been enabled to procure sterility of the hands in seventy-eight per cent of the cases. He commends this method as the safest and the quickest for thoroughly disinfecting the hands and the skin when infected with decomposed substances.

FRAC TURE OF THE PAT ELLA.

Prichard (Bristol Medico-Chirurgical Journal, June, 1899) reports two cases of fracture of the patella treated by wiring, and exhibited skigrams showing the admirable results which can be obtained by this method. He thus summarizes the various methods of treatment for this injury:

First, the plan without operation. This, the old one, consists of rest with the application of splint and bandages. There are various excellent ways of drawing the fragments together, and perhaps in almost the majority of the cases this method is the one to be recommended, and it often gives fair results; but the best result that can be hoped for is a
ligamentous union with more or less impairment of extension, and the probability is that the individual will never be able to run or climb a ladder.

Secondly, subcutaneous silk ligature, by surrounding the kneecap either laterally or vertically by a stout silk cord. In the latter case the ligature is passed by means of a strong needle right into the joint and is left in, resting on the condyles. The author states that he has had no personal experience of this plan, but that he does not imagine it would be successful in many cases when the tilting of the fragments and the in-dipping of the fibrous covering are considered. The tilting is present in most cases and is sometimes remarkable, as in one case which was wired, where the fractured surface of the upper fragment was directly forwards. The dipping in of the fibrous covering has been present and has given some trouble in all cases the author has seen operated on.

Thirdly, the recently recommended method of massage of the thigh muscles and passive movement of the knee from the commencement of the case. This is advocated by those who think that the cause of bad results in cases that have not been operated on is to some extent atrophy of the quadriceps, and contraction of the fascia from want of use. Prichard has nothing to say about this treatment from his own experience. He believes that it can never result in bony union if the fragments have been separated, and a ligamentous union can never give the support that a bony one gives.

Fourthly, the method of an open operation and sewing up the fibrous covering and split lateral expansion of the quadriceps by buried sutures. This has, to the author's mind, little to recommend it in comparison with wiring, as the operation would be as severe, and the result not so secure.

Fifthly, wiring. It is usual to make a longitudinal incision and then carefully to scrape away all material between the fragments, to bore and pass the wire, then to irrigate the joint, washing out all clot, then tighten the wire. Prichard always puts a drainage-tube into the joint on the outer side, and removes it in twenty-four hours. One can generally rely upon a single stout silver wire. A good plan, when the lower fragment is small, is to pass two wires through one hole in the lower, and separate them to pass through two holes in the upper.

Wiring the patella should not be done too soon after the accident; the joint should be allowed at least forty-eight hours to begin to recover from the immediate effect of the injury.

The operation should not be undertaken by any one who has not complete confidence in his antiseptics and in his carpentering skill, nor in cases where the general health is not good; but as far as the author's experience and ideas go, it is the right thing to recommend in young adults who have to use their legs in earning their living, or who wish to be able to indulge in a fair amount of active exercise.

HEMORRHAGE FOLLOWING ADENOID OPERATIONS.

Martin (The Laryngoscope, July, 1899) reports three cases of hemorrhage following adenoid operations. He had been operating on these growths seven years before he came to a complete realization of what unpleasant consequences could ensue.

The first case, sixteen years old, had been subjected to cauterization of the turbinates for several months before he came under Martin's charge. Some pharyngeal adenoids were removed with the Gottstein knife under cocaine anesthesia. There was free bleeding for a few moments, but it speedily ceased. The patient was placed in the recumbent position for perhaps an hour and a half without further manifestations of hemorrhage. When he came to rise the blood gushed freely from his nostrils and mouth. The recumbent position was followed by immediate cessation of the bleeding. After fifteen minutes waiting the patient was allowed to sit up, and an effort was made to examine his throat with a mirror, but the bleeding started afresh and the patient fainted. After some trouble a plug was inserted into the posterior nares. This was left in place for thirty-six hours. On removal there was no recurrence. About one pint of blood was lost.

The second case was seven years old. Pharyngeal adenoids were removed with almost no bleeding. Two days later there was sufficient hemorrhage to alarm the family; but on inspecting the patient it was found not alarming in any way. Two days following this there was another slight hemorrhage. On the following day, on attempting to examine the nose, the bleeding recurred. As it ceased spontaneously, no effort was made to plug. Later in the same day there was profuse bleeding, amounting to about three-quarters of a pint. The nostril was then plugged posteriorly and
anteriorly, and the child recovered without recurrence.

The third case was six years old. She was operated on for recurrent adenoids. Six days later there was slight hemorrhage from the nose. On the ninth day after the operation there was a very profuse bleeding, amounting to more than half a pint. This patient recovered without plugging.

---

**Reviews.**

**AN INTRODUCTION TO DERMATOLOGY.** By Norman Walker, M.D. With Illustrations in Colored Plates and in Black and White.

Bristol: John Wright & Co, 1899.

The appearance of still another book upon diseases of the skin is fair evidence of the fact that authors and publishers believe that the profession are willing to buy additional volumes dealing with this topic, in order if possible to gain more information concerning a class of ailments which comes before many practitioners.

The present volume is practically a reproduction of the lectures which Dr. Walker has given to his students in Edinburgh. There are several points about it which strike us favorably from the standpoint of the general practitioner: First, that the colored plates, while not particularly handsome, show the diseases they represent in a very lifelike way; secondly, that many prescriptions are introduced which have been found useful by the author in his practice; and thirdly, that the many illustrations in black and white are also excellent.

The frontispiece, or colored plate, seems to us an instance of the author putting his worst foot foremost, as it by no means shows the conditions it is designed to illustrate as clearly as some others which are contained in the volume.

As a brief summary of diseases of the skin, this book can be cordially recommended to the profession; indeed, considering its size and the character of the plates, it is probably the most useful book for its cost that can be obtained.

Four parties may be congratulated upon the publication of this essay, which is a large octavo volume of nearly 350 pages. The first one who deserves congratulation is the author; the second, the committee of the College of Physicians who awarded the prize to so deserving an effort; the third party benefited is the profession in general; and last, but not least, have patients suffering from this disease cause for congratulation in its publication, for intelligent physicians who read it will have a better idea of the condition which they are called upon to treat by climatic and other measures than they could possess before it had been read, unless they have traveled widely and visited many of the great sanitariums for tuberculosis. The author brings to his work enthusiasm and experience. On this side of the Atlantic he has had opportunities to study disease of the lungs, and at one time he was assistant to Professor Dettweiler, of the Falkenstein Sanatorium, in Germany.

The book opens with a dedication to the hygienists, statesmen, and philanthropists, and the many noble men and women inside and outside of the medical profession, who labor and have labored, on behalf of tuberculous invalids, and who have demonstrated that consumption is a preventable and curable disease. In the latter part of this dedication it seems to us that the author has struck the key-note which it would be well for all physicians to remember. In the chapters which follow he deals with certain interesting data in the history of tuberculosis, then takes up its mortality, and then the particulars of its curability. In the succeeding chapters he deals with its communicability, the various prophylactic rules and laws which should be instituted for its preventive treatment, and then passes on to a consideration of the more important sanitariums of Europe, United States, and Canada for the cure of tubercular patients. After discussing these he considers aerotherapeutics, rest cure, and various remedial measures other than drugs for the treatment of this class of patients, and deals exhaustively with the various complications of tuberculosis.

There are few persons in the profession who will not be interested in the perusal of the pages of this book. It is a must excellent work.

**PYORRHEA ALVEOLARIS, AND ITS RELATIONS TO GENERAL MEDICINE.** By John Fitzgerald, L.D.S.

This is a tiny volume of sixty pages, in which no attempt has been made to write an exhaustive treatise upon this condition, but
simply to point out the bearings of this disease upon medical practice and to indicate how it may be treated. Practically the volume is a reprint of certain articles which have appeared in the London Clinical Journal, and the instruments and methods which are advised are of much greater interest to the dentist than to the general practitioner, although the book is designed to enable the general practitioner to treat the condition.

This is a little manual, earlier editions of which we have noticed favorably in the Therapeutic Gazette. We do not know of any small work upon massage which will give the physician and nurse so much practical information as this one, as the descriptions of the various movements and the illustrations which accompany these descriptions are adequate, and yet not so exhaustive as to be confusing and impracticable. The book is one which can be cordially recommended, and will do much good, we doubt not, in increasing the use of these valuable measures in the cure of disease.

About a year ago we noticed the appearance of the first edition of this little work, which contains at its end a considerable bibliography of the literature of this well known and persistent affection, and which, after discussing the various causes of the disease, embodies the views of the author and then details the treatment which he has found useful both in the way of local applications, general treatment, and dietetics. The fact that a second edition has been called for within a year shows that the author has dealt with the subject in a manner which has attracted attention.

A MANUAL OF DISEASES OF THE NERVOUS SYSTEM.

As the title indicates this, the first, volume of the third edition of Sir William Gowers' classic manual upon diseases of the nervous system deals with diseases of the nerves and spinal cord. The privilege is not given to many physicians of presenting the profession with a work which at once gives evidence of great literary research and ample clinical facilities. Those who are familiar with Dr. Gowers' work note that in some places he deals with certain matters in a somewhat dictatorial and dogmatic manner, controvverting views held by other eminent neurologists, but it must be admitted by all persons that the volume is a landmark in the progress of modern neurology. It is needless in this instance to deal with the qualifications which have made the book famous and popular. We are told in the preface of the third edition that every chapter has been subjected to careful revision, and that numerous additions have been made to the text as the result of advances in neurological science and experience. The very great advances which have been made in our methods of studying diseases of the nerves and spinal cord have, of course, necessitated a very great revision of certain portions of the earlier editions, and we find that in the description of the disease known as locomotor ataxia, the newer views concerning this malady are recognized and the important point is emphasized that it consists of the degeneration of the posterior columns of the cord or the peripheral sensory nerves, or both. Too often physicians regard the condition as purely a spinal one, when in reality the peripheral nervous manifestations are the more noteworthy.

It is a pity that in such an excellent book so little attention has been paid to the character of the illustrations. A number of the new ones are much better executed than the old ones, but all of them fail to approach the text in quality. Many of the pictures of patients, as for example those on pages 34 and 35, are little more than rude outline drawings.

THE SERUM DIAGNOSIS OF DISEASE. By Richard C. Cabot, M.D.

Dr. Cabot in his short prefatory note informs us that this book is nothing but a compilation, its aim being to bring together in convenient form the results of the immense amount of work which has been done upon serum diagnosis since 1896.

While it is true that it is to a large extent a compilation, the pages of the work show very clearly that Dr. Cabot has had a large amount of personal practical experience in serum diagnosis, and therefore the compila-
tion possesses all the greater value because his personal experience has enabled him to separate the tares from the wheat.

Dr. Cabot is a thorough believer in the value of serum diagnosis. We are informed as an instance of how useful it may be that when he arrived at Ponce he found at the United States General Hospital several hundred fever cases, all of whom were receiving large doses of quinine, because the diagnosis between typhoid and malaria had never been clearly established, owing to the lack of materials for producing the serum reaction. He examined 177 cases at this hospital, and found not a single instance of malaria among them, while ninety per cent of those examined showed prompt and intense reaction for typhoid fever. As a result of this a clear diagnosis was at once obtained, and the wholesale administration of quinine was checked and clear ideas as to the proper method of treatment were reached. So, too, it was possible on several occasions to make a differential diagnosis between typhoid fever with jaundice and yellow fever. As he also well points out, had the typhoid reaction been employed, it would not have been necessary to keep the Spanish prisoners nearly a week in Portsmouth, New Hampshire, in order that a diagnosis between typhoid, malaria, and yellow fever could be reached.

Finally, it is worth while to note the assertion with which he closes some introductory remarks, namely, that the cultures used for this test can be kept indefinitely at room temperature, and that the whole process can easily and safely be carried out by the physician in his office without any laboratory facilities, and with half the skill and labor necessary to examine urinary sediment. Dr. Cabot deserves an immense amount of credit for having placed before us this excellent summary of the knowledge of this most important subject.

ESSENTIALS OF MODERN TREATMENT OF DISEASE.
By K. M. Nadkarni.

This is an extended therapeutic index for the treatment of diseases, arranged alphabetically, and containing many prescriptions for the administration of curative remedies. It seems to be based largely upon the experience of others, and a good deal of information, as is stated in the preface, has been taken from standard works upon practice and therapeutics. In the middle of the volume are several advertising pages of drug firms and publishers. We doubt not that amongst Indian practitioners who wish a book of this character it will prove successful, although we cannot see that it possesses any advantage over somewhat larger and smaller manuals which are at present employed by British and American physicians.

The object of this book is quite evident from its title-page. Its contents are, naturally, of much greater interest to dentists than physicians, although it is not to be forgotten that much dental damage can be prevented if physicians in treating their patients pay more attention to the condition of the mouth and teeth. The volume contains copious directions as to the means by which the teeth may be preserved from decay by proper cleanliness and general medical care.

Bristol, England: John Wright & Company.

This is a tiny little volume of seventy-one pages, about 4 x 3 inches in size, and although it is necessarily closely printed it does not contain very much information in regard to surgery. On the other hand, it may be said that it has been compiled by a well known surgeon who has endeavored in its pages to embody what he thinks are a number of important points. Nearly every sentence begins with “Do not” or “Never forget to” do this or do that. It is a small enough volume to go into the vest pocket, and doubtless will be largely used by students.

We have also received three other little volumes, one entitled Golden Rules of Gynecology, another Golden Rules of Obstetrical Practice, and a third Golden Rules of Medical Practice, which belong to the same series. That upon Surgery, however, seems to us to be by long odds the best of the series.

MINERAL WATERS OF THE UNITED STATES AND THEIR THERAPEUTIC USES. To which is added an Appendix on Potable Waters. By James K. Crook, A.M., M.D.

This is a large octavo volume of nearly 600 pages, printed in excellent type and on good paper, and with the object of providing the profession with information concerning mineral waters of the United States. The book opens with a general consideration of
mineral waters, and then deals with the various mineral ingredients which they contain and also with the gases with which they are sometimes charged. After this, chapters are devoted to the therapeutics of the various mineral waters, and then follow others in which the subjects of baths, douches, and other medicinal measures are discussed. In Part Two we find a description of the mineral springs and wells of the United States, with the topographical and climatic features of each in each State and Territory, the various springs being arranged in alphabetical order according to States. It is a matter of interest in looking over this list to find how rich certain States are in valuable mineral springs, and how few springs possessing medicinal properties are to be found in others. The character of the information in this part consists, first, in a description of the railroad facilities for getting to the resort, the distance from near-by prominent points, the post-office address, and then follows an analysis of the water, with a description of the conditions in which it is generally employed.

So far as we know, this is the only complete description of the various remedial waters of this country which is in existence. The work of compiling it must have been very great, and considering the difficulties of writing upon such a subject, the author has certainly completed his task very well indeed. It would be better for their patients if physicians would keep themselves informed as to the various hydrotherapeutic measures which are described, and which do not have to be used in many instances at the springs themselves, but can be employed at home.

This is probably the most exhaustive book in the English language dealing with this subject. Although there are a number of translations of foreign works which have been presented to American readers, we believe this is the first one of any size or importance which has been prepared by an American author.

The manner of its publication is almost that of an edition de luxe, as the large octavo pages, good-sized type, and heavy paper make it a very handsome illustration of what the medical book-maker's art is to-day. In addition to the colored plates and black and white drawings which illustrate the difficult and somewhat complex subject with which it deals, there are also a number of ordinary colored illustrations which add materially to the value of the book. So far as we have been able to see, every picture shows exactly what it is intended to illustrate, and almost every page indicates the fact that the author is thoroughly in touch with modern neurological views and with the technique of the preparation of neurological specimens. Considering the great advances which have been made recently in our knowledge of the minute anatomy of the nervous system, the book appears at a most opportune time. Of course, much of the material which it contains is in the nature of a compilation, but as the compiling has been well done, this is an advantage rather than a disadvantage. Towards the close of the book the various staining methods are given for the preparation and examination of neurological specimens, and a copious index closes its pages.

Much credit is to be given to the author for its preparation, and almost as much to the publishers for their generosity in having provided so handsome a presentation of an important topic.

Bristol, England: John Wright & Co.

Six editions of this little handbook designed for mothers and nurses have appeared since January, 1891, and therefore it has evidently proved itself of value to this class of caretakers and readers. An important point evidently recognized by the authoress and insisted upon in her preface, is the well known fact that no two babies are exactly alike, and that every child has its own peculiarities which must be carefully watched and studied; and again, that young mothers are very much influenced by the views of monthly nurses, who if they are well trained can be of distinct educational value to the maternal mind, and if they are poorly trained have an opportunity for perpetuating certain superstitions in regard to childbed and child-growth which are sometimes unfortunate in their results.

This little book does not profess to be an advanced work upon the care of infancy, nor is it to be employed by physicians, although we are told that in the preparation of the text the authoress has had the advantage of having her pages revised by a competent medical man.
Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFORD, M.A., M.D. OXON, M.R.C.P.
LOND.

Another medical year has just drawn to a close, and the benediction has been pronounced over its departure by the recent meeting of the British Medical Association at Portsmouth. The burning question of the year has been the evolution of the new university for London; the Commissioners have at any rate succeeded in finding a local habitation for the university in the desolate buildings of the Imperial Institute. Whether a great teaching center in this site is to supplant or merely supplement the work of already existing centers is a point on which we are still in the dark. There is a pretty widespread feeling that in maintaining so large a number of independent teaching institutions as at present, medicine in the metropolis is laboring under a heavy economical disadvantage. So much of the fees of students is absorbed in the teaching of such costly subjects as physiology, that little is forthcoming for the furtherance of clinical research, and in this field at the present time we are in urgent danger of falling behind other nations. There can be little doubt that some degree of concentration of the early medical subjects is the best and indeed the only way of solving this difficulty, but we do not think that complete concentration into a single center is desirable, as so large a body of students could not be effectively handled by a single set of teachers; and therein is the crux, as the Government clearly cannot be expected to provide several such centers, bearing in mind the price of a single site in the metropolis, and teaching institutions, like individuals, have no liking for the principle of “survival of the fittest” when applied to themselves. There is reason to believe that before the end of the current year we shall be in possession of the Commissioners’ complete scheme.

King’s College Hospital has just appointed a special-physician for diseases of children. To you in America, and to several continental nations, this would hardly seem worthy of comment, but as a fact this is the first appointment of the kind in a general medical school that has been made at any hospital in Great Britain. The natural evolution of the appointment should be towards a professorship in the same subject in association with the hospital clinic.

The lay papers have been in their element recently with startling announcements of the discovery of the causation of cancer, and promises of its disappearance from the catalogue of ills that flesh is heir to. It need hardly be said that the observer to whom these soul-stirring discoveries are attributed is guiltless of inspiring these effusions. The plain fact, as detailed by Dr. Lambert Lack in his disclaimers, is as follows: Having been long impressed by the belief that the epithelial cells of cancer were themselves the sole infective agents, that this cancer epithelium was practically normal epithelium only out of place, and that from the very commencement of the cancer it was growing in the lymph space, Dr. Lack concluded that if normal epithelium by some accidental means should obtain entrance into the lymph spaces it would find no barrier to its continued growth, and would produce all the phenomena of cancer. Accordingly Dr. Lack set to work to test his conclusion. He prepared an emulsion of the healthy epithelial cells from the ovary of a healthy rabbit, and placed them in the animal’s peritoneum. The animal died fourteen months later, and on examination masses of growth were found in the abdominal and thoracic cavities having the characteristic features of typical ovarian cancer. The Journal of Pathology contains a more extensive account of this experiment. We sincerely sympathize with Dr. Lack in the unfortunate publicity that has befallen his experiment, before he has had an opportunity of confirming or condemning it by a series of experiments on the same lines.

Dr. Jardine read an interesting paper at the Edinburgh Obstetrical Society on the treatment of eclampsia by saline injections. He held that in most cases that came under treatment before convulsions came on it was easy to abort the attack by purgatives, diaphoretics, and diuretics, eliminating the poison, but that if convulsions had already set in it was a much more difficult task to obtain diuresis. With this end in view he had employed large saline injections into the subcutaneous tissues. In most of the cases he had used a mixture of one part of bicarbonate of potash to three of common salt, a teaspoonful to the pint of sterilized water at 100° F. The potash was added because of its diuretic action, and no poisonous effects had been observed. If such occurred it was
always possible to use acetate of sodium, which though less diuretic was also less toxic than the acetate of potash. The injection could be made in any part where the tissue was lax. After delivery Dr. Jardine had selected the lax abdominal wall, and before delivery the edge of the breast, and in either situation it was quite easy to run in a pint in four minutes, and the whole would be absorbed in from fifteen to twenty minutes. It is difficult to subscribe to Dr. Jardine’s suggestion that the bicarbonate of potash may help to neutralize the poison in the blood. Moreover, on the evidence supplied by Dr. Jardine in his communication it is difficult to see that the addition of bicarbonate of potash carries with it any special advantage over the normal saline solution. Dr. Jardine had found benefit from the employment of veratrum along with the saline injections, but he was far from considering it a specific; certainly it was preferable to morphine, which, though concealing the outward expression of the condition, served assuredly to aggravate the cause.

Dr. Yonge sounds a note of warning against the common belief that orthoform as a local anesthetic to ulcerated surfaces is quite innocuous. It seems that in a small percentage of cases orthoform, like pure carbolic acid, tends to produce sloughing from local necrosis; the process can, however, be readily checked by withdrawing the drug. Brocq also has observed an inflammatory reaction of the skin, and Epstein vomiting, collapse, and other disorders when the drug is given by the mouth.

PARIS LETTER.

Dr. Plicque, of Paris, has published recently in the Presse Médicale an article on the treatment of fibrous phthisis. A few words on the various points shown up by Dr. Plicque may prove of interest to our readers. Fibrous phthisis is more troublesome but less dangerous than the ordinary form. The cough is more painful, more hacking; hemoptysis is more frequent, abundant, and tenacious. Slight attacks of congestion are often observed, but with all this the local lesions do not increase in intensity. The reason for this benign tendency is that, as Landouzy has said, there is a tendency to sclerosis due to the general condition of the patient. On account of its special attributes, this form of phthisis offers special indications, and what is less known, special contraindications. The air cure should be followed out with certain precautions. No very high altitudes, no exaggeration in muscular exercise should be practiced, for the open country is quite sufficient in spring, summer, and autumn. In winter the patient should be sent to Pau, Mentone, Cannes, Grasse, San Remo. The fits of coughing should be suppressed as much as possible, and excessive talking is to be discountenanced.

The food cure cannot be applied here as in most cases. The kidney, without being very much attacked, is in far from perfect condition, and all excessive formation of toxins is apt to irritate the glandular tissue and provoke albuminuria. It would seem that milk is indicated, but its use cannot be continued very long, as it is apt to cause weakness, excessive perspiration, and polyuria. Raw meat, powdered vegetables, the yolks of very fresh eggs, and white meats are easily taken and do not produce any bad results. Any symptoms of intolerance, such as palpitations, vertigo, and expectoration, are easily stopped by the use of a milk diet.

All the preceding remarks apply as well to the use of drugs.

On account of the congestive tendencies, such drugs as iodine, sulphur, and arsenic should be used with care. For instance, mineral waters containing arsenic or sulphur should be recommended with caution. Le Mont Dore, La Bourboule Luchon, Les Eaux-Bonnes, offer a certain efficacy in some forms of fibrous phthisis, but when employed without moderation may cause congestion and hemorrhage. One of the best drugs that can be used against dyspnea is iodide of sodium or iodide of potassium. Dr. Potain, the celebrated heart and lung specialist, uses the following formula:

- Chloride of sodium, 10 grammes;
- Bromide of sodium, 5 grammes;
- Iodide of sodium, 1.50 grammes;
- Distilled water, 100 grammes.

From one to three teaspoonfuls a day in a cup of milk.

Iodoform would also seem to be indicated on account of its tendency to prevent hemorrhage. Five to ten centigrammes a day is sufficient. For instance:

- Iodoform, 0.05;
- Dover’s powder, 0.10;
- Tolu balsam, q. s.

For one soft pill. One or two daily.

If there is intolerance, hypodermic inje-
tions consisting of the following may be employed:

- Iodoform, 1 gramme;
- Sweet almond oil, 20 Cc.

One injection daily of one cubic centimeter.

In case of hemorrhage, fractional doses of ipecacuanha are efficacious.

Lastly, revulsion is often useful. The thermodiathermy is to be preferred to blisters or tincture of iodine on account of the condition of the kidney.

At a recent meeting of the Academy of Medicine Professor Landouzy presented, on behalf of Dr. Carsoute, a physician of the hospitals of Marseilles, a note on the use of carbonate of creosote in the treatment of non-tuberculous bronchopneumonias. The doses given varied from five, ten, fifteen, up to twenty grammes. Given in this manner, this drug brings about the asepsis of the pulmonary tract, and there is consequently a lowering of the temperature, a shortening of the duration of the illness, and a rapid amelioration which is shown by the disappearance of the functional and physical symptoms.

A recent treatment for chronic urethritis is that indicated by Dr. Desnos, surgeon of the hospitals, and Dr. Guillon, of Paris. Picric acid is the agent used, and the authors of this new treatment have insisted on its harmless ness when cautiously employed. Instillations are made every other day with a one- or two- per-cent solution, twenty to eighty drops being used. With the first group of seventeen chronic cases, thirteen cures have been obtained, two noticeable ameliorations, and two failures, which were operated upon later. When the urethritis is of tuberculous origin the results are not so brilliant, only two cures out of twelve cases being obtained.

At the meeting that took place at the Academy of Medicine on July 18, Professor Robin and Dr. Leredde spoke of the work they have done in establishing a correlation between diseases of the skin and diseases of the stomach. In 424 cases of stomach affections, cutaneous manifestations were found in 129. Thirty patients suffering from prurigo, lichen, or eczema were examined as to the condition of their gastric juice, and in all there were found butyric and lactic acid. This form of dyspepsia is very often latent. By administering jaborandi the perspiration was increased, and on examination was found to contain a greater coefficient of acidity than is usually found. Perhaps the alteration of the skin is due to this excess of excretion. The treatment was a direct result of this conception, and out of seventeen cases there were seven cures. As a means of checking gastric fermentation Dr. Robin employed fluorde of ammonium:

- Fluoride of ammonium, 0.20 centigramme;
- Distilled water, 300 grammes.

Two large spoonfuls to be taken every day.

As a means of checking butyric fermentation Dr. Robin has found it advisable to give iodide of bismuth and cinchonine 1 to 5 centigrammes, or iodated sulphur 10 to 20 centigrammes, which was given in the middle of each meal. In old cases sterilized milk is beneficial. As a means of employing local treatment the best method is to apply on the skin silicated water containing carbonate and silicate of calcium. This preparation is dusted over the diseased surface, and an application is used as a sort of varnish, containing a greater or smaller quantity of aloe, according to the duration of the affection.

It is a well known fact that the number of patients going to the spas in France has not increased in as noticeable a manner as in Germany. The causes of this are manifold. The administrations of the different establishments are not so progressive in France as in Germany. There is not that constant striving to improve the conditions of the watering-place. But outside this purely material cause and the fact that some waters are no longer thought to be efficacious, another reason is that the French physician graduates without having any definite idea about the value of the various waters that can be used in France, and not having sufficiently precise indications on this subject, he prefers to abstain from ordering them. There has been instituted recently a committee of well known physicians, under whose management a series of excursions to the waters will be undertaken. On September 2 a trip will be taken to the waters of the central part of France and of Auvergne, such as Neris, La Bourboule, Mont Dore, St. Nectaire, Royat, Chatel Guyon, Vichy, Bourbon Laachambault, Bourbon-Lancy, St. Honor, Pouges. Professor Landouzy, of the Faculty of Medicine of Paris, will accompany the group of physicians and students who will subscribe to this trip, and at the different spas will give an explanation of their usefulness and action. This excursion will last eleven days, and will end at Pouges.

ON THE DESTRUCTION OF MOSQUITOES—A CONTRIBUTION TO THE STUDY OF CULVICIDAL SUBSTANCES, BEARING UPON THE PREVENTION OF MALARIA BY THIS MEANS.

By Dr. A. Celli, Professor of Hygiene, University of Rome, and Dr. O. Casagrandi, Assistant in the Institute of Hygiene, University of Rome.

(Translated from the Italian by Dr. J. E. Eyre, of Rome.)

The pain and discomfort produced by the bites of mosquitoes in man have been universally recognized even from ancient times. And now, after the latest studies, by which it has been proved that the insects of this family of Culicide are the definitive host of the malarial parasites, to the above must be added the enormous injuries they cause by their bites.

The destruction, therefore, of these insects which are so injurious to us, and nothing but injurious, has become a social necessity.

Popular experience has already made some attempts in this direction, which we shall have occasion to refer to later on. But to-day an opposite experimental study that, succeeding, would have an importance analogous to that which disinfecting substances...
have had for bacterial diseases, has become more than ever essential.

It is necessary, however, above all, to fix well certain principal biological conditions in which the mosquitoes exist that are to be destroyed; and more especially the genus and species to which they appertain, the age, time of captivity, certain pathological states, and the stage of development.

Genus and Species.—It not being known whether to the means of destruction the various genera and species oppose an equal resistance, the necessity arises of indicating clearly and distinctly the zoological names of the mosquitoes that are experimented upon.

Age.—This has an influence in the larval stage as well as in that of the winged insect. For example, we find that the minimum resistance, other things being equal, is offered by the larva directly it comes out of the egg, and by the mosquito soon after it develops from the nympha; and the maximum by the larva which is about to become a nympha, and by the perfect insect captured in the air.

Time of Captivity.—It is rarely that the laboratory environment can be as favorable to the life of the mosquitoes as the natural environment; therefore both the larva and the perfect mosquitoes directly they are captured have always a greater resistance to the culicid substances; and in consequence all our observations refer to a material freshly arrived from the Roman Campagna.

Pathological States.—Sometimes directly after they are found, more frequently after they have been in the laboratory, the larvae present, in greater or less numbers, a waxy whitening of their bodies, in which state they offer less resistance to the destroying agents. And, above all, it is necessary to note particularly the stage of development—that is, whether they be eggs, larvæ, nymphae, or perfect mosquitoes; in this last stage they live in the air, in the others they live in water; hence the necessity of varying the culicid substances according to the environment where they live. And even when they are in the water the resistance of the larva varies very much from that of the nympha, these latter being, as a rule, more resistant than the former.

Thus the classification of the culicid substances must be made on the basis of the stage of development of the insects which one wishes to destroy. We therefore have:

1. Substances that kill the eggs.
2. Substances that kill the larvæ.
3. Substances that kill the larvæ and nymphae.
4. Substances that kill the perfect mosquitoes.

Substances that Kill the Eggs of Mosquitoes.

We have experimented on the eggs of the Culex pipiens, the most easy variety to be obtained in quantities, and we have found that those substances, even in greater proportions, which kill, as we shall see, the adult larvæ, are not always sufficient to kill the eggs.

However, the very young larvæ, especially directly after they are born, resist but little the action of these substances, even when very diluted. This, from the practical point of view, is important, inasmuch as it assures us that even with very dilute substances, and consequently cheap ones, when the eggs do not die, the larvæ die directly they come out of the eggs; which practically is the equivalent of the destruction of a species.

Substances that Kill the Larvæ of Mosquitoes.

The popular experiments made for this purpose in America are reduced to the employment of a very common substance in use in that country fifty years ago, but never universally diffused—viz., petroleum—and to the more recent use of permanganate of potassium.

The history of the other researches already made for the same end is very short, inasmuch as it is limited, as far as we know, to the American studies.

In America mosquitoes are a regular plague in many localities, and consequently several entomologists have tried to free these places from them—thus, in 1890, Robert H. Lamborn,* and under his direction Aaron, Week, Bentenmüller, Macaulay, McCook; and later† Howard (1893), Herbert Osborn (1892–96),‡ chief of the Division of Entomology, Department of Agriculture, have carried out researches. The results were not, in truth, very comforting, and they refer almost exclusively to the use of petroleum.

Thus Aaron says that, in 1890, he had found that a drop of petroleum (!) dropped into a puddle of ten square feet killed in fifteen minutes (!) all the larvæ and nymphae of the mosquitoes which existed there, while

---

*“Dragon Flies vs. Mosquitoes. Can the Mosquito Pest be Mitigated?” New York, 1890.
the Crustaceae and the larvae of the Odonate or Libellulide survived.

Howard states that he succeeded, in 1893, in killing with petroleum all the insects in a pond of sixty square feet; and in the following year, having on June 4, in the neighborhood of Washington, covered a pond of 100 square feet with a stratum of petroleum (five gallons), in June and July he saw no mosquitoes develop, though they usually infest that place. Consequently, he maintains that with a little petroleum one can free many localities from mosquitoes.

Osborn also maintains that "probably the best and easiest of all remedies against mosquitoes is the use of petroleum on the surface of ponds." And he adds that this use was already known; but having made, in 1892, experiments on a large scale, he found that an ounce of petroleum for every fifteen square feet of surface of a small pond was sufficient for this purpose for a month, but that sometimes it was necessary to renew it more frequently. Since 1892, having repeated his experiments, he assures us that he has succeeded with petroleum alone in freeing two localities from mosquitoes; so that, in 1896, he proposed to experiment with it on large ponds, the cost being insignificant, and it being possible to scatter it with a large broom against the wind from the dikes or from a boat.

What the result of these experiments has been we do not know; nor does the above mentioned very minute and accurate review of Nuttal, which has lately appeared, mention it.

For our part, after many trials, we have convinced ourselves that, apart from the question of expense, which outside of America is very considerable, the action of petroleum in destroying the larvae of mosquitoes does not certainly occupy the first place, and it is also true that in some cases the use of other substances would not be more advisable.

Up till now very few substances have been used for this purpose in this relation; we know only that Whitfield in Atlantic City has added green vitriol to water containing larvae of mosquitoes.

We know of no precise researches made with potassium permanganate, one of the substances much extolled for the destruction of mosquitoes.

Among the indirect researches that are directed to destroy the malarial germs in a locality by means of permanent drainage (bonifica), we may mention that Lanzi and Terrigi, in 1873, extensively applied a treatment of caustic lime mixed with water in the excavations in the Colosseum, and it was then observed that the workmen employed in the excavations did not suffer from malarial fever. An analogous experiment with identical result was subsequently made by Salisbury.*

We, however, have wished to make a study, as complete as possible, of all those chemical substances which, owing to their more or less low price, could be freely used for the destruction of mosquitoes in water.

As the criterion for judging the larvicidal action of a given substance, we have taken the time it takes to kill the larvae, considering that substance inefficacious which does not kill them at most within three days (seventy-two hours). And, consequently, according to this criterion all the substances up till now tested by us are divided into two great categories:

A. SUBSTANCES THAT DO NOT KILL THE LARVAE OF MOSQUITOES.

Among these, which now amount to 198, we find, besides the 167 coloring substances: Permanganate of potash in solution \( \frac{1}{1000} \) and \( \frac{1}{10000} \). Arsenious acid in ammoniacal solution \( 10:1000 \). Various soaps (except an extract of tobacco).

Petroleum itself (so extolled by the Americans), also in the proportion of 0.05 per 100 c.m.q. of surface at a temperature of 18°C. Ammonia (1:100 at 18°C); tannic acid (1:10000); borax (1:1000).

Gaseous water (with \( \text{CO}_2 \)), sulphurous water (with \( \text{H}_2\text{S} \)).

Analogously we have observed that the larvae and nymphs of mosquitoes live very well in the Aquend Albul of Tivoli and in sulphurous waters of the same type.

B. SUBSTANCES WHICH KILL THE LARVAE OF MOSQUITOES.

We here give the list of these substances, dividing them into two tables, in the first of which (see Table I) we enumerate various chemical substances, and a few vegetable infusions; in the second (see Table II) we place the most efficacious of the staining substances derived from coal tar; in the third (see Table III) we analyze the action of the most active among these last.

</table>

**Once for all we state that the results synthetically and summarily shown in the tables represent the mean of the experiments, always repeated many times, and with a large number of culicides.**

From the three preceding tables it results that:

1. Among the mineral substances, permanganate of potash even in the considerable dose of 5:1000 is, among the larvicidal substances, one of the slowest to act; lime, sulphate of iron and of copper, and NH₃, act rather slowly even in very large proportions; sulphurous water, even when not saturated with SO₃, is one of the most active larvicidal substances; corrosive sublimate in the strong dose of 1:1000 kills the larvae slowly, but not the nymph.

2. Among the vegetable substances, very potent poisons to the larvae are the leaves of strong tobacco and some commercial insecticide powders, which are made of the expanded flowers of chrysanthemums. Other commercial insecticide powders were either less active or altogether inefficacious. Then comes the commercial extract of tobacco, and finally a saturated aqueous infusion of quassia, of Solanum nigrum, and of Daphne guilturnum. We shall see that the above mentioned powders in larger proportions also kill the nymph.

3. Of the aniline colors (blue, violet, red, yellow, and green) that we have experimented with, the two which have the most energetic action are the galloil of Wellert-Meer-of Uerdingen, and the green malachite of Actiengesellschaft für Anilinfabrikation of Berlin. Of these two colors the galloil is the more active. Its certainly larvicidal dose is 0.0062:1000; that of the former is 0.0125; the minimum larvicidal dose of the first may descend to 0.0007, while that of the second is never less than 0.0037.

**SUBSTANCES WHICH KILL LARVAE AND NYMPHÆ OF MOSQUITOES.**

We have already seen that some substances which readily kill the larvae have no action on the nymphae, so that these may complete their development and transform themselves into the aerial insect.

We shall now see which are the substances that kill both the larvae and the nymphae of mosquitoes; they are arranged in the following table according to the time required for killing the larvaes:
TABLE IV.

Action of colloidal substances on larvae and nymphs of mosquitoes (C. pipiens, C. quinquefasciatus) at the ordinary temperature (18° to 30° C.).

</tbody>
</table>

From the preceding table it clearly results that:

1. The destruction of the nymphae is in general a rather difficult task, this being the stage of development in which the mosquitoes oppose the greatest resistance to the destroying agents. In fact, as a rule, the nymphae take a longer time to die than the larvae, except that in oily substances, which float on the surface, where the nymphae generally go to breathe, the latter die before or at the same time as the larvae.

2. Classifying the substances used according to the time required to kill the larvae, we find in the first line sulphurous water saturated with SO2, and then potassium permanganate mixed with HCl. The permanganate alone acts much more weakly even in greater proportions (2:100-1:100). Very efficacious are light oily substances, among which is petroleum—that, however, must act at the ordinary temperature, in the proportion at least of 0.10 Cc. per 100 c.m.q. of surface. Common oil has a perfectly analogous action.

Salt water, which at 5-10:100 (see Table I) kills the larvae in fifteen hours, in concentrated solution kills the larvae in thirty minutes and the nymphae in an hour.

Very active also are the above mentioned commercial insecticide powders obtained from chrysanthemum flowers; they act through their active principle, which is soluble in water, and is a true larvical and nymphical poison.

- Caustic lime and ammonia only act in strong doses, and thus also chlorite and carburet of lime.

3. Of the most potent disinfectants of bacteria, formalin and lysol are not very active as colloidal substances, and corrosive sublimate, as we have already seen (see Table I), is even less so.

4. The nympha stage being very transitory, in the destruction of mosquitoes it may be neglected in practice.

(A) CONDITIONS THAT MODIFY THE ACTIVITY OF THE SUBSTANCES WHICH KILL LARVAE AND NYMPHAE OF MOSQUITOES.

Naturally these conditions are multiple, and we here mention the principal ones: the frequency or not of cooperating substances, the so-called mordants, direct sunlight, the physical and chemical properties of the waters, the state of the waters—that is, the mode in which they are taken—and the age of the larvae.

1. Mordants.—Table IV demonstrates that the permanganate of potash, while it has by itself alone a rather weak larvicidal action, is much strengthened in this action by the addition of hydrochloric acid. But the addition or not of these mordants acquires special importance in the presence of the aufline colors, which we have already seen were capable of killing the eggs or the larvae of mosquitoes. Consequently we have thoroughly studied this argument for the above mentioned two most active colors; and from the very numerous experiments we have been able undoubtedly to conclude that:

(a) Sulphate of iron, lime, chloride of sodium, bisulphate of potash, chromic acid, sulphuric acid, added in equal. or double proportion to gallo1, hasten a little the action to the extent that in a solution of gallo 0.50 or of mordant 0.1:1000, the larvae die in the least time that the gallo1 alone requires—that is, in six hours. Chloride of lime, ammonia, iron, alum, borax, a mixture of bichromate of potash and sulphuric acid (1 to 3), do not augment the colloidal action of gallo1, just as neither, nor the other
mordants mentioned, in the proportions indicated, augment it with green malachite.

(6) Thus varying contemporaneously the quantity, per mille, of the color and of the mordant (selecting, for example, sulphate of iron), and varying either only the quantity of the color or only the quantity of the mordant, this does not produce a notable or decided auxiliary action. Perhaps the mordant is of some use in the minimum larvicidal solutions, rendering them more certainly fatal within seventy-two hours. But with such small results it is not worth the trouble or the expense to add the mordants. This is tantamount to saying that where they exist, for example, in salt water marshes or lakes, it is all the better.

2. Direct Sunlight.—This does not injure for a certain time the efficacy of the colors; on the contrary, in the weak coloring solutions in marsh waters, retarding the putrefaction, it makes the larvicidal action last for a long time. Neither does it disturb the action of petroleum, which, however, is disturbed, as we shall see, by the temperature, and therefore also by the summer sun.

3. Physical and Chemical Properties of the Waters where Larvae and Nymphs of Mosquitoes Live.—One readily understands that they have an importance of the first order. Among the physical properties we note at once:

(a) Temperature.

(b) Turbidity by suspension of earthy particles. As regards this, we shall refer to it in the next section, where we shall treat of the influence of earth on some of the larvicidal substances.

That the chemical properties of the waters, where the mosquitoes pass a long portion of their lives, have much influence on the mode and on the time of their eventual destruction is readily understood.

For example, permanganate of potash, having to oxidize the organic substances, will be more readily destroyed in marsh waters, and also in sulphurous waters. Petroleum itself, evaporating and oxidizing, does not very long remain unaltered on the surface of waters. Lime and the alkalies in general combine with the CO₂ which, by the organic decomposition of the earth and of the waters, actively develops.

Among the aniline colors there are some that are little stable; it therefore became necessary, for the practical scope of these researches, to investigate how they act in marsh waters eventually putrid, and in sulphurous waters, which are, as we have said, with us so frequently the nests of mosquitoes. We knew already that the salt of the sea water of the marine ponds along our malarious coast acts as a mordant.

(c) Marsh waters. By repeated experiments we have persuaded ourselves that both

</tr>
</tbody>
</table>

The above figures clearly show the influence of temperature on the power of the various substances most efficacious in killing larvae and nymphs of mosquitoes. With the rise of temperature, even within the limits of our hot summer, the time of destruction both of the larvae and of the nymph is shortened, except that with petroleum, which, therefore, does not act chemically, but only mechanically—that is, subtracting the atmospheric air by means of its impermeable stratum.

gallol and green malachite, indifferently with or without a mordant, act well even in marsh waters; for example, in the proportion of 0.025:1000 the first repeatedly killed the larva of Culex in eight to ten hours, the second in ten to twelve hours. The same can be said of the above mentioned insecticide powders.

(d) Sulphurous waters (Aque Albule of Tivoli). With the same two colors, in similar proportions, they act like the marsh waters.
Experiments on a large scale made in the Campagna within ponds of marshy and sulphurous waters have confirmed the above mentioned favorable results obtained in the laboratory researches. The insecticide powders also act in sulphurous waters.

(c) Putrid waters. Putrefaction diminishes the efficacy of petroleum, perhaps oxidizing it, and renders it less durable. Instead, even in putrid liquids, galloil at 0.50:1000 acts equally well; still more, it slackens the decomposition. Nevertheless, both in the weaker coloring solutions and in those losing their color through time, directly putrefaction intervenes the larvicidal efficacy of this substance is arrested and suddenly interrupted. The same happens for the mentioned insecticide powders.

4. State of the Waters (Mode of Taking, etc.).—Above all, it is important to observe whether the earth in the bottom of the marshes, ponds, or lakes, or that in suspension in the waters, alters the larvicidal energy, especially of the anilne colors. For this purpose many comparative experiments were made in large vessels, with or without earth at the bottom, with the two most efficacious colors, mixed or not with mordant, and used in different proportions. We have been thus able to demonstrate that with the presence of earth in the bottom of the vessels the larvicidal action does not change, and with galloil it is maintained, as we shall see, for a long time in proportion to the depth of the water above the earth.

The extension of the surface of the waters in relation to their quantity acquires a notable value for those substances which act on the surface, cutting off or diminishing the area and the respiratory air that the larva and nymphae absolutely require.

In practice there are the two extreme cases of lakes and ponds with a deep bottom, or of small puddles and shallow pools with a large and more or less irregular surface. In both cases the action of petroleum was the object of special researches.

From these figures it clearly results that petroleum develops a purely mechanical larvicidal action—that is, subtracting the air. The quantity of it necessary is therefore proportionate to the surface of water to be disinfected. And if the stratum does not cover the whole surface from contact with the atmosphere, its action immediately becomes nil.

5. Age of the Larvae.—As we have said in the beginning and have repeated, aprópos of the destruction of the eggs, the very young or young larvae are much more easily destroyed than the adult; this is clearly shown in the following table:

<table>
<thead>

Substances which Kill the Larvae and Nymphae of the Genus Anopheles.—Up till now we have seen that the larva and nymphae of this genus have the habit of living rather isolated, and they are never found in the malarogenous puddles and ponds in such large numbers as those of the genus Culex. Consequently we have not been able to experiment on material so exuberant as that of the other genera. Nevertheless, of the very young and adult larva, as well as of the nymphae of the two species Claviger and Bifurcatus, we have had sufficient to test them with lime, permanganate of potash, common salt, sulphate of iron, sulphurous water, sublimate, lysol, common oil and petroleum, infusion of tobacco, galloil, and green malachite; and always contemporaneously, for control, we have tested the same substances with the very young and the adult larva of the genus Culex.

From the mean of all the experiments we have come to the conclusion that the larva
and nymphæ of the genus Anopheles do not oppose a resistance substantially different to the deleterious action of those among the most efficacious larvicial substances.

(b) DURATION OF ACTION OF THE SUBSTANCES WHICH KILL LARVÆ AND NYMPHÆ OF MOSQUITOES.

This condition is very important from the practical point of view, especially in relation to the cost of the destruction of mosquitoes.

One clearly sees that of the various substances above used for several days in succession the first to lose its larvicidal action is petroleum, which, evaporating and decomposing, no longer covers all the surface of the water. In fact, in a dose of 0.20 Cc. per 100 c.m.q. it lasts for two days at 18° C.; but at 35° to 57° C. it no longer acts after one day, as also in the minimum larvicidal dose of 0.10 Cc. per 100 c.m.q. The duration of this larvicidal action of petroleum was then compared with that of the two most efficacious coloring substances. For this purpose many experiments were instituted in conditions very similar to those of the Campagna—that is, with marsh waters and with sulphurous waters in large receptacles with and without earth at the bottom. It was found that in marsh waters with earth at the bottom:

- Gallol, at 0.50:1000 after 45 days is very active.
- " 0.05:1000 14 " 4 " 4 " 4 "
- " 0.0125:1000 4 " 4 " 4 "
- Green malachite, " 0.50:1000 12 " 8 " 4 " 4 "
- " 0.25:1000 12 " 8 " 4 " 4 "

For each of these colors, if the solution is in a very thin stratum above an abundant bottom of earth, the duration of the larvicidal action is shortened a little.

Also, in sulphurous waters, as in those which are very marshy, the duration of the effect of the gallol is longer than that of green malachite. Indeed, one sees at a glance that the latter loses its color immediately in aqueous solution, still more if the mordant sulphate of iron be added, and most rapidly after lime, does the color disappear. So that once more we observe the superiority of gallol over green malachite for this larvicidal scope. In all the above mentioned cases the larvicidal efficacy ceased instantaneously, as has been recorded,

directly the putrefaction of the water began, under the form of a film of proteid on the surface.

The earth of the bottom, the direct sunlight, preventing this appearance of putrefaction even in very dilute coloring solutions, aid in prolonging the larvicidal efficacy of the substances mentioned. And in conclusion, from all our experiments, it undoubtedly results that gallol especially, among all the substances used by us for killing the larvae of mosquitoes, has the most durable larvicidal efficacy.

(c) Practicability.

Above all, it is necessary to know whether the substances largely employable in the Campagna with a larvicidal purpose, wherever the waters are the nest of the larvae of mosquitoes, are of very easy use; whether they poison these waters eventually, potable for animals and man; whether they injure the plants of irriguous cultures, such as artificial meadow-lands (marcite) and rice-fields.

Among all the most efficacious larvicidal substances, sulphur dioxide is not practicable, because to produce burning sulphur more or less cumbersome apparatus are nec-
essary; and even if we were able to have the liquid contained in iron cylinders its use in the Campagna would not be easy, apart also from the question of price. Certainly it would be useful for destroying other insects noxious to agriculture; but it injures the vegetation, as we have proved by an experiment made on a large scale. If this vegetation be of that marshy nature which obstructs the canals and the course of the waters, it would be beneficial, but *vice versa*, if that of the irriguous cultures it would be injurious. For all these reasons the use of sulphur dioxide for larvicidal purposes can only be very limited.

Petroleum, instead, is of relatively easy use, even in large ponds and lakes. It does not kill the fish or the other inferior animals. The herbivora avoid drinking it. In stagnant waters the vegetation, sometimes very abundant on the surface, obstructs its mechanical action; in waters even slightly running its superficial stratum must be frequently or continuously renewed. We may add that its action is proportionate to its diffusibility on the surface of the waters. Consequently, the lighter the petroleum the better it acts; but in this case the action lasts for a shorter time. For example, in commerce there are some qualities of petroleum which, thrown on water, do not spread, but remain in the form of more or less large drops. These are least indicated for the destruction of the larvae.

The insecticide powders previously mentioned are very easily used, and when swallowed even in big doses by herbivora they are not poisonous; but they are poisonous to some worms, Mollusca, and fishes.

The coloring substances, when they are, like the two above mentioned, very soluble and diffusible in water, are also very practicable and easily used. In practice it is convenient first to make very concentrated solutions, and then dilute these in the waters where the larvae are to be destroyed. The colorimetric criterion is very convenient for regulating the proportion. Or better, the proportions per mille indicated in Table III are dissolved in water. Then one observes the shades of color of these solutions; and in this way with the eye one can obtain on a large scale the proportion necessary to be used, without his being obliged first to measure the quantity of the water to be freed from the larvae. They destroy also all the animals which live in the water, including the fish and the tadpoles; consequently, contemporaneously are destroyed many other animals noxious to agriculture—that, from the point of view of aquarian economy, is not little.

As to the poisonous effect on mammifers, we already know that green malachite is innocuous.

We have found that gallol is innocuous in a dose of 0.20 grain hypodermically or by the mouth to a rabbit or a guinea-pig of 400 grammes, and 0.50 gr. to a dog of three kilogrammes. The minimum lethal dose for a guinea-pig and for a rabbit of the above weight is 0.50 gr., and death takes place in convulsions, as with carbolic acid.

At the autopsy we noted, when the inoculation had been made subcutaneously, a gelatinous edema of the color of the injected material in the inoculated spot, the viscera in general of a violet color, the bladder full of colored urine, flaccid kidneys, etc. When the inoculation had been made by the mouth the same conditions were noted, except those subcutaneous, besides a slight catarrhal condition of the intestine.

A larger dose than 0.50 gr. by the mouth caused vomiting in dogs; but less than 5 grs. did not kill them.

As to the doses in which gallol dissolved in water with a larvicidal scope is innocuous for mammifers, we have had the proof.

In one of our experiments made on a large scale for destroying the larvae, it happened that a flock of sheep drank the water without suffering any injury.

These colors even in their strongest solutions do not in the least damage herbaceous plants, and consequently not the herbage of the Marcite, which has very well supported repeated and abundant consecutive irrigations.

For deciding the use of the most efficacious larvicidal substances the last word belongs to the

(d) Price.

We give the cost of the most easily used larvicidal substances, in their minimum lethal doses, at the rate of the current price:

PER CUBIC METER.
The great cost, in the larvicidal dose necessary, puts out of the question all the mineral substances, including the cheapest—chloride of lime. Evidently the vegetable powders, the coloring substances, and petroleum are the cheapest for making applications on a large scale. The chrysanthemum plants from which the said powders are obtained can be cultivated by us on a large scale, and therefore these powders will be had at a much lower price than they cost at present in the market.

The price of the two coloring substances is not definite, but when manufactured in large quantities it will become less.

An exact comparison cannot be made concerning the price between the coloring substances and petroleum, inasmuch as the latter acts in surface or by suspension, the former in solution. In any case the selection must be regulated according to circumstances, taking into consideration especially, as we have already stated, the duration of action, the conditions of the water, and its agricultural uses.

Substances that Kill Perfect Mosquitoes.

Popular experience has specially preoccupied itself in finding substances which keep away mosquitoes from man and from his habitations. Thus it is known that the shepherds and peasants of the Roman Campagna endeavor to protect themselves from mosquitoes with fire and with smoke; for this purpose the straw huts in which they live, with the fire which gives off smoke in the middle of the floor so that the huts become full of smoke, are better than the masonry habitations, built without any special attempt at defense against malaria.

Lind (1779) asserts, besides, that wearing round the neck a little bag containing garlic and camphor serves as a prophylactic against the seasonal fevers! This was also recommended a few years ago by Mantegazza to our poor workers in the rice-fields. Thus also in Sardinia, at Crosei and Dorgâlì, to protect themselves from mosquitoes, the people cut slices of garlic and rub them on the face and the other uncovered parts of the body, as also the bedsteads of the beds on which they sleep.

It is also known that some individuals have such cutaneous exhalations that they are never bitten by mosquitoes; and that the various substances which are sold for procuring quiet sleep in places infested with mosquitoes, rather than killing them, are more or less successful in causing them to disappear.

As far as we know, up to the present no experimental researches have been made with the purpose of killing the aerial mosquitoes. There are a few indirect observations, like those of Silvestri, also cited by D'Abbadie (1882), on the immunity of the workers in the sulphur mines of Sicily from malaria. And among the substances used for keeping away mosquitoes we may mention that Weeder* (1880) extols the burning of the leaves of Mentha pulegium (or its essential oil); Campbell (1891) praises much the smoke of chamomile, because it killed the mosquitoes in a room so that they could be swept away.

But wishing precisely and exactly to judge the real culicidal action of whatever substance, it is necessary to differentiate well apparent death from real death. This distinction is fundamental both for classifying in the order of their true culicidal action the various substances, and for not accrediting such an action to substances which in reality produce only apparent death. It is necessary, therefore, to experiment in such a way as not to fall into errors.

From a practical point of view we distinguish the substances used into three categories—that is, odors, fumes, and gases.

We have experimented with the odors in the small space of a bell-glass, placed over the odorous substance, in its turn contained in a glass capsule covered with a cloth; for the fumes and gases we have, instead, used a chamber of wood and glass, of the capacity of about 100 liters, invented and described by Rosenthal† for the scholastic demonstrations of the laws of ventilation in rooms. We thus had a space very similar to a living-room, and perfectly lighted, so that we were able to follow with the eye the behavior of the mosquitoes under the action of the various substances.

Each time we experimented with mosquitoes of several species captured in the Campagna, and to assure ourselves, when the experiment was finished, whether the

---

* Nuttal, loc. cit.
† "Vorlesungen über die öffentliche und private Gesundheitspflege," Erlangen, 1887, p. 185.
animals were really dead or not, we collected them in receptacles, where we subsequently saw if they revived or not.

We thus have been able to observe whether the corners, eventually the fissures where the mosquitoes nest, offered more or less of a refuge against the volatile substances also efficacious against them.

Therefore, the results given below represent what in reality is obtained when the whole space of a restricted room has been invaded by a given odorous or vaporous substance up to complete saturation. For this purpose we burned, for example, within the above mentioned chamber, tobacco, pyrethrum powder, or resin, 2 grs.; chamomile flowers or quassia wood, 5 grs.; various leaves, flowers of chrysanthemum, and ordinary wood, 25 grs.; of the so-called culicidal cones we burnt no less than two within this small space.

Their mode and time of action are given in the following table:

</table>

In this table the various substances are arranged in the order in which they produced real death of the aerial mosquitoes. It is thus seen that we have among the odors turpentine and iodoform; among the fumes that of tobacco, whose infusion we have already seen is a potent larvicide; and among the gases sulphurous oxide, which we have already found very efficacious against the larvae and nymphs. Other substances very practical and consequently very useful are, among the odors, nutmeg, camphor, and garlic, the latter two already sanctioned by popular experience; among the fumes, those of chrysanthemum flowers, of fresh eucalyptus leaves, quassia wood, and pyrethrum. It is not, therefore, necessary for us to spend money in buying commercial preparations—every one can procure them himself; and in cases of necessity he can make use of the smoke of firewood, which by popular experience has been found useful in the huts where our cultivators of the agro romano have lived for centuries.

Of the gases, the most practical, and at the same time efficacious as a culicide, are the fumes of burning sulphur; sulphur of carbon, so much extolled as an insecticide, is inactive in a large space, owing to its heaviness.

Definitely, the destruction of mosquitoes in houses is much more easy than any bacterial disinfection of habitations whatsoever.

CONCLUSIONS AND PRACTICAL COROLLARIES.

1. Of the whole period of the cycle of development of mosquitoes, the stages in which they are most easily destroyed are those of the larva and of the aerial mosquito; in the former stage they are the more easily killed the younger they are.

2. To kill the larvae, among all the very numerous substances experimented with we have in decreasing order of culicidal action:
   (a) Among the mineral substances: sulphurous oxide, permanganate of potash with hydrochloric acid, common salt, potash, am-
monia, carburet of lime, corrosive sublimate, chloride of lime; and then the bisulphites, sulphate of iron and of copper, lime, bichromate of potash, sodium sulphite. (d) Among the organic substances: powders of the unexpanded flowers of chrysanthemums, tobacco, petroleum and oils, formalin, cresol, certain aniline colors (gallol, green malachite), coal tar.

Taking into consideration, however, the necessary larvicide dose, the practicability, and the price, all the mineral and some of the organic substances must be excluded, and there remain the vegetable powders, petroleum, and the aniline colors.

3. To kill the aerial mosquitoes we have odors, fumes, and gases. In the first place, among the odors we have the essential oil of turpentine, iodoform, menthol, nutmeg, camphor, garlic; among the fumes that of tobacco, chrysanthemum powder, fresh leaves of eucalyptus, quassia wood, pyrethrum powder; among the gases, sulphurized oxide. It is, however, to be noted that for these odors, fumes, or gases to exercise their culicidal action they must fill or saturate the whole ambient; otherwise they produce only apparent death, or at the most only a culicifugal action, which sometimes in houses may be useful in protecting man from being bitten by mosquitoes, and in preventing the latter infecting him, when they have sucked the blood of malarious persons.

4. The problem of the destruction of mosquitoes is experimentally soluble; but practically it will only be so when economic interest desires it. In this latter sense it is remarkable that the old larvicide use of petroleum has not become much diffused even in those places where it is very cheap; and it is probable that those substances which destroy other aquatic creatures injurious to agriculture will be preferred, and perhaps still more those which can be had by cultivating them on the spot. For example, by growing on a large scale the chrysanthemum plants (Chrysanthemum cinerarifolium, etc.), from which the culicidal powders are obtained, it is very probable that one will succeed in making the malarial place itself produce that substance which will free it of the mosquitoes that infest it.

5. The opportune season for killing the larvae is the winter, when they are in least number in the waters, and new generations are not born; consequently, this is the time most easy for attacking them. Destroying mosquitoes in houses is always possible, but to have the greatest effect it is also best to do it in the winter, when they all take refuge in inhabited places, or wherever else they repair. The more complete knowledge of their habits—that is, of the places where and the season when they nest—will aid very much the success of this destruction, which, even in the most favorable cases—that is, when hydraulic improvement (bonifica) will have exhausted its task—will not be such an easy work on a large scale as some persons believe and boast. Nevertheless, after the treasures spent by nations and private individuals for preserving vines from the oidium, the peronospora, and the phylloxera, we may hope that something will be done for protecting the life of man from the mosquitoes of malaria.*

REMOVAL OF TUMOR OF SUPRARENAL CAPSULE:†

Mr. Robson related two cases in which he has successfully removed a tumor of the suprarenal capsule. One was in a woman forty-seven years of age, operated on in 1891, who died of recurrence of sarcoma and exhaustion a few months after the operation. His second case, a woman of sixty-two, operated on in 1897, is still living and well. The tumor removed was a struma lipomatosa supra renallis, described by Virchow.

In the first case the suprarenal growth was so firmly fixed to the top of the kidney that that organ had to be removed as well, but in the second case only a wedge-shaped piece from the top of the kidney was removed with the tumor. In the patient who is still living the removal of the tumor had not been followed by any pathological phenomena.

He also related a third operation, in which his colleague, Mr. Ward, removed a sarcoma of the adrenal from a child aged twelve months. The child died from shock within a few hours.

He gave a table of eight cases, of which four had recovered and four died. He be-

* As these researches of ours on the destruction of mosquitoes are scarcely begun, and as we are continuing them, we shall be grateful to all those manufacturers of chemical products who will send us samples of their products, which owing to their uniform of price can be used on a vast scale, according to the criteria we have expounded.
† Abstract of a paper read before the British Medical Association, August, 1899.
lieved these to represent the whole operative surgery of the suprarenal capsule. He said that he thought the true secret of success lay in operating at an early stage of the growth, as in his second case.

After describing the operated cases Mr. Mayo Robson mentioned a case of sarcoma of the suprarenal capsule which he had observed throughout its whole course in 1875, and from this case and others that he had seen he drew attention to the following symptoms:

(a) Shoulder-tip pain. This was so well marked in all the three cases that he thinks it could not have been a mere coincidence, but was probably dependent on the disease. It may be explained by the fact of small branches of the phrenic nerve passing to the semilunar ganglia.

(b) Pain radiating from the tumor across the abdomen and to the back, not along the genito-ocular nerve.

(c) Marked loss of flesh.

(d) Nervous depression with loss of strength.

(e) Digestive disturbance, flatulence, and vomiting.

(f) Presence of a tumor beneath the costal margin, right or left, at first movable with respiration, but soon becoming fixed. It can be felt in the costovertebral angle posteriorly and can be pushed forward into the hollow of the palpating hand in front of the abdomen.

(g) Absence of urinary and of gall-bladder symptoms.

He concluded his paper by describing the technique of the operation.

ON MODERN TREATMENT OF UTERINE CANCER.*

BY THOMAS MORE MADDEN, M.D., F.R.C.S. ED., Obstetric Physician and Gynecologist, Mater Misericordiae Hospital, Dublin.

In the gynecological wards of the Mater Misericordiae Hospital, Dublin, which have been under the writer's charge for the last quarter of a century, a very distinct increase has been observed within the past six years in the frequency of cases of cancer of the uterus. In the present communication is submitted a résumé of my clinical experience of the curative and palliative measures now available in the treatment of that disease. Amongst others, the former of those thus referred to include: (a) Early amputation of the cancerous cervix; (b) hysterectomy by vaginal or abdominal routes; (c) electrolysis; (d) escharotics, actual and potential; (e) injection of absolute alcohol into substance of cancerous growth; (f) the employment of celandine, methylene blue, and some other remedies for which specifically curative effects have recently been claimed.

Of all these methods of treatment, however, there is but one on which I place any very wide or general reliance in the treatment of uterine cancer. The disease in the vast majority of instances primarily manifests itself in the cicatricial tissues resulting from parturient lacerations of the cervix uteri. Therein it very frequently remains localized for a time, sufficiently long to enable its timely detection by proper recognition of topical evidence, and above all by that microscopic examination of the scrapings of the affected surface which should be invariably resorted to in all cervical lesions occurring in patients approaching to or beyond the climacteric period. If thus early recognized, incipient cancerous degeneration may in a large proportion of cases be effectually arrested, before any malignant invasion of the superior uterine zones has occurred, by its timely and complete removal and the free cauterization of the divided surface well above the area of cancerous infection.

The advantages of this practice are sufficiently shown by the facts that, first, in the large number of instances in which it has been resorted to the mortality of the operation was nil; secondly, that in two-thirds of those cases the patients remained free from any recurrence of cancerous disease in the uterus or elsewhere as long as they remained under his observation—namely, for periods varying from two to ten years after the operation. These results contrast favorably with any that can be claimed for hysterectomy under similar circumstances, and hence I believe that operation in such cases should be restricted to those less frequent instances in which cancer primarily attacks the fundus or body of the uterus, or in which it has recurred there after the removal of the cervix. Under such conditions the abdominal hysterectomy operation affords greater facilities than the now generally preferred vaginal procedure for that thorough exploration and complete extirpation of any accessible implicated lymphatic by which we may hope to
secure immunity from eventual recurrence of the malignant disease.

Although the immediate mortality of hysterectomy for carcinoma as well as for other causes has, and more especially by the vaginal method, been now reduced to a very small percentage, the eventual or curative results of such operations are by no means as satisfactorily proven as would now seem to be generally held. If the disease be thus dealt with in its incipient stage, and when distinctly confined to the cervix, there is no reason in the present state of abdominal and pelvic surgery to doubt the curative results thus claimed. But could not those results equally well, and with still less risk, be attained in such cases by the removal of the cervix alone? On the other hand, if in the statistics which are apparently held to justify an indiscriminate resort to hysterectomy in cases of uterine cancer be included cases of long-standing malignant disease in which the upper portion of the uterus and its connections have been extensively implicated, the matter assumes a very different aspect. Bearing in mind the intimate and widespread lymphatic relations of the uterus, it is difficult to realize how under such circumstances a disease so prone to disseminate itself can, generally speaking, be so thoroughly removed from a network of adjoining lymphatic glands, and vessels apparently beyond reach of surgical interposition, as to warrant the confident assertions of eventually curative results that are made by some hysterectomists, of whose bona fides there is no question, but whose conclusions might probably be considerably modified by reexamination of their cases at a longer interval after operation. At the same time the writer fully recognizes the expediency of hysterectomy in those appropriate instances before referred to, viz., in the earlier stages of fundal uterine cancer as well as in some cases of cervical epithelioma in which the disease has recurred in the fundus or body of the uterus after removal of the cervix.

With such exceptions, however, having in view the common origin and general localization for a time of uterine cancer within the cervical zone and the advantages to be derived from the adoption of effective topical measures in such cases, I am convinced of the importance of the early extirpation of the incipient cervical disease. Moreover, as a preventive expedient even in cases where no evidence of malignancy is discoverable, the complete removal of all cicatricial cervi-

cal tissues resulting from traumatic injuries that might possibly otherwise eventually become the seat of cancerous disease is wise. These tissues may in such cases be more effectually dealt with by écrasure and thermo-
cautery than by cervical trachelorrhaphy, especially in women beyond the climacteric period.

In the concluding part of the paper the uses of electrolysis, chloride of zinc, and local injections of absolute alcohol, as well as the employment of celandine, methylene blue, orthoform, and various other remedies now advocated for the mitigation of hemorrhage or discharge, or for relief of pain, in inoperable cases of uterine cancer, are discussed.

**INTESTINAL ANTISEPTICS IN TYPHOID FEVER.**

By M. M. Pearson, M.D., Bristol, Tenn.

There are no classes of remedies that have been brought so prominently before the profession within the last few years as germicides and antiseptics, both local and internal. It is to the latter and to the so-called intestinal antiseptics that this paper will be devoted. The vast number of the proposed agents so enthusiastically urged by members of the profession makes a strong argument that discredits their efficiency.

Since the knowledge of the bacillary origin of Asiatic cholera and allied diseases of the intestinal tract, and even before, on the assumption that these were supposed to be of bacillary origin, the bacteriologist in his laboratory and the clinician have continued in their extended and painstaking efforts until they have embraced every conceivable drug of real or supposed antiseptic properties. It is also to be observed, and with special reference to this subject, that the phenol group is at the base of most of them, and likewise is the most abused class in the entire materia medica list.

The chemist is unable to master this subject for the reason that the behavior of a given drug within the test-tube and its behavior after it reaches the intestinal tract may be different and is entirely conjectural; and after all the clinician is the great "leveler of truth." It has not infrequently been heralded that the ideal drug or combination of drugs has been discovered, but no sooner was the test of experience tried than each in its turn has taken its place upon the "doubt-
ful list,” and beyond this we have been unable to go. We are apprised of the fact that the task is far more difficult than was at first dreamed of, and to-day the subject of intestinal antiseptics can at best be said to be in the experimental stage. In other words, the question of intestinal antiseptics “is the substance of things hoped for, the evidence of things not seen.”

By making a review of this subject we will find our German confrères have instituted a practice based on the antiseptic principle, and which was known as the “specific treatment.” It consisted in giving ten grains of calomel on the first day of a case of typhoid fever, eight grains on the second day, and so on for each succeeding day for a period of about one week. This treatment had many advocates, and among them were Leibermeister and other notable German and American authorities. This treatment was regulated to conform with their knowledge of the pathology of this disease, and at the time was opposed by many and subsequently condemned, because it was not found to be scientific, and likewise did not afford the best results clinically. Having proven unworthy of the title of “specific,” it was followed by what was known as the “German specific treatment.” This well understood mode of treatment has not only had the approbation of the Germans, but has met with great favor within the United States, and is more generally employed to-day than any other line of treatment, particularly in the rural districts, where the doctor does his own dispensing, being both convenient and practical.

Statistics as furnished by certain institutions and individual members of the profession are unreliable, inasmuch as typhoid fever in every locality and in every epidemic is a law unto itself. Many cases as we well know do well with the worst of treatment, and bad with the best of treatment. The treatment of a few cases, or a few hundred cases, may mislead, as it did our lamented Pepper.

The “German specific treatment” consists in the administration of compound tincture of iodine combined with carbolic acid in the proportion of two to one, which combination is to be frequently administered. In the discussion of the present subject this treatment is selected because of its general and continued use, and because it fairly represents the principle embraced in this subject. It was on this idea that the late William Pepper, one of the most distinguished of American authors and practitioners, was led to adopt the use of nitrate of silver, which he advises in Pepper's System of Medicine, and which he so enthusiastically indorsed. He reports having treated one hundred consecutive cases without a death. At this time, or perhaps a little later, Henry used thymol and reported about the same results. But at present we know of no author advancing either of these drugs to the exclusion of others; and the authors themselves later disclaimed them as not fulfilling the promise set forth for them, and as not bearing the test of experience.

Woodbridge, of Ohio, with his fifteen-minute triturates and three-days' cure, makes a record surpassing anything yet in point of time and results. He claims for his method that it is antiseptic and eliminative, and as such abortive. We cannot admit the first proposition to be true, nor grant the latter.

William F. Waugh declares in favor of sulphocarbolate of zinc as the long looked for boon in intestinal antiseptics. Yet the great bulk of the profession have failed to find it such, and after the use of all these antiseptics the bacillary invaders remain as secure and firmly fixed in their favorite habitat, the meshes and substance of the glands of Peyer and the solitary glands, as ever.

At the present day there is not a teacher of practice in any of the reputable schools, or hospitals of like standing, or a reputable author, who vouches for the so-called antiseptic treatment in typhoid. The author of this paper has a report from about twenty teachers of practice in the leading medical colleges of the United States, who were recently asked the questions, first, What is the best treatment of typhoid fever? and, secondly, Is calomel useful and indispensable? Without exception the answer to the first question was the "Brand method," and to the second, No; except in one or two cases in which an occasional dose of calomel was permissible in the beginning, as a purge, but not as a routine treatment.

The papers read before the American Medical Association at the last two meetings disclosed the common unanimity of opinion, and no man of national reputation advocated any of the methods briefly outlined in the context of this paper, and only inadvertently referred to the so-called antiseptic treatment.

When we come to consider the question on its merits, it does not stand to reason, theory, or common sense, as a plan of practice. Should experience and practice yield positive results, then it would be that theory
could be surrendered to plausibility; but when neither establish the claims that carry any degree of conviction, then both should be relinquished.

By an intestinal antiseptic is meant an agent or drug that will arrest putrefaction and the supplicative process in the intestinal tract, the result of the presence and multiplication of organisms which are eliminated and destroyed. Foster’s Practical Therapeutics says on this subject: “Certain drugs locally applied in proper strength are destructive of microorganisms of local infection, and at the same time safe to the patient. This applies to surgical antiseptics. But with infectious conditions within the body, the difficulty in the way of attainment is greater. It is little to be wondered at that the intestinal antiseptics and internal antiseptics of the present day are not much advanced beyond the period of theory, and in the opinion of members of the profession are hardly likely to advance much further.”

Let us see why this is true. The same author, in speaking further on this subject, says: “It is necessary to say that the devitalizing agent in disinfection is a chemical action between two bodies, and it is essential that their molecules should be brought into contact with one another. The obstacle is in the difficulty of reaching the microorganisms with the drug without previous occurrence of chemical changes in it, as would render it almost or quite inert. Second, the great danger of doing serious injury to the patient by giving drugs in quantity sufficiently large to reach the organisms and destroy them.”

Let us analyze the iodine and carbolic treatment of typhoid from a chemical standpoint, and as an antiseptic, through which medium it must act. There is no proof that it acts through the blood, and it is not so claimed by the advocates of this practice. Pursuing the advised mode of administration, which is two drops of the solution every two hours, and we will suppose this is cumulative and remains in the intestinal tract, and that none of it is absorbed, the patient will have in all thirty-six drops. As to the relative value of these drugs as antiseptics, Sternberg says that iodine, in a two per-cent solution, will destroy microorganisms of pus in two hours; and further, that it does not rank as an energetic antiseptic. Of carbolic acid Foster’s Therapeutics says that it does not rank as an antiseptic as compared with the metallic salts, and for the disinfection of excreta a five-per-cent solution, equal in volume to the quantity to be disinfected, should stand four hours; and further, that it has no influence whatever upon either general or internal antiseptics.

Beginning at the mouth with the thirty-six drops of the mixture for the entire twenty-four hours, and which is destined to reach the small intestines, let us see what we encounter. Approximating the secretion of saliva for the twenty-four hours to be 1280 grammes, gastric juice 6000 grammes, pancreatic juice 800 grammes, bile 1000 grammes, and water in food and drink 2000 grammes, we get in all a total of 11,080 grammes, or nearly three gallons of liquid. True, the secretions are diminished, while the water taken is markedly increased, so that, to be safe, we will say that the total is two gallons. But this is not all. There are the various constituents of the food, the various actions and reactions, chemical and physiological, met with in the stomach, mouth, and intestines, together with various bacteria, some of which are pathogenic, so that the object sought cannot be hoped for, much less attained, owing to the great dilution of the antiseptic.

But this is not all of the carbolic acid and iodine treatment, nor all for the vast phenol group. If iodine and carbolic acid reach the intestines as such, and especially in their high dilutions, would they add to the development or the destruction of the bacilli? If salol, which is favored by Anders in his recent and very excellent work, is converted into salicylic acid and carbolic acid in the small intestines, is it a curative agent or a promoter of the growth and multiplication of organisms, upon which the virulence of the disease depends, by furnishing a pabulum favorable to their growth and development? To say the least, the experiment appears to be dangerous, and for the following reasons:

Frankel, a recognized authority on bacteriology, says on the subject of typhoid culture, now being considered for purposes more especially diagnostic, that “Chantemesse and Widal, for instance, have stated that typhoid bacilli can flourish on two per cent of carbolic acid gelatin, while the majority of other bacilli do not flourish.” The same author also speaks of the culture medium of Holtz, which varies from the one above in some minor essentials, yet contains iodine, however, in a weaker solution. Ball, an American author, on the same subject in his second edition of Essentials of Bacteriology, says “that gelatin, which has added to it ten per
cent of carabolic acid, will allow the typhoid bacilli to develop, other similar bacilli being destroyed." Reeve, in his Medical Microscopy, quotes from the observation of Chantemesse and Widal in reference to their culture medium, and to Widal is due the discovery of the reaction test in typhoid.

Hence it would appear that carabolic acid, instead of destroying the organisms in question, would not prevent their growth, although the contents of the intestines might approach the strength of a two-per-cent solution, at which strength the typhoid germ has been known to survive and develop.

But by some it may be held that the good effect of this treatment is due to the iodine. In 1895 the subject of typhoid culture was taken up by Elsner, and he considered the potato gelatin of Holtz, referred to by Frankel, as the best medium up to that time. The appearance of the typhoid bacilli was not in his opinion sufficiently distinctive, especially when the carabolic acid was added, and after a long search he found iodide of potassium, in the strength of one per cent, an ideal substitute.

Let us now view this subject from another standpoint, and with special reference to true etiology and pathology. Supposing that we could reach the diseased glands within the intestinal tract, to what extent would we be able to influence the course and duration of the disease? It is more than probable that the bacilli of typhoid gain entrance to the system through the glands of the small intestines, and that here is the prime point of infection and dissemination, and we grant this; yet it does not prove the absolute efficiency of local treatment or that typhoid can be or is aborted. More than likely there are other agencies more deadly than the typhoid bacilli, per se, and in no wise should our sole aim be directed to the removal and destruction of these germs, which, no doubt, if it could be accomplished, would be important. Infectious diseases, of which typhoid is a typical entity, mean more than a localized trouble. The bacilli some seem to suppose are merely lodged upon the mucous membrane of these glands, but even before the febrile stage begins, or, in other words, during the period of incubation, they have passed beneath the mucous membrane into the glandular substance and may be found in the spleen, mesentery glands, gallbladder, and also in the blood. The theory that the live organisms infect the glands and the ptoamines circulate through the system, thus producing the various morbid phenomena, is not well taken, since the living organisms have been found in almost every part of the body, and occasionally in the blood. We are forced to the conclusion that typhoid fever is as much a systemic, although self-limited, disease as syphilis, and treatment directed purely to the local lesion, and based on that principle, is as much a folly as the treatment of a chancre for the permanent cure of syphilis. Likewise, the rule holds good with special reference to the mere local treatment of diphtheria, and it is also a fact that none of the infectious diseases are influenced by a mere local treatment. The local and so-called antiseptic treatment of diphtheria has been abandoned, and in its stead serum-therapy has been adopted. The opportunity for local treatment in this disease is excellent as compared to typhoid fever.

H. A. West, professor of theory and practice in the University of Texas, in a paper before the American Medical Association, lays down the following propositions on typhoid: First, it is a specific infectious disease, and, with the exception of malaria, there is no disease of this class that can be jugulated by the action of drugs; secondly, the long period of incubation and the prolonged insidious onset characteristic of this disease give ample time for the infectious organisms to pass beyond the intestines into the other tissues, where they cannot be reached by way of the gastrointestinal canal; thirdly, there is no evidence to prove the potency of any drug for the destruction of the pathogenic agent in the intestines, when given in doses which would not be toxic to the infected person; fourthly, there is no drug known to me which will destroy the typhoid bacilli through the circulation, and that will destroy the bacilli after they have reached the glandular organs; fifthly, my experience with the formulas which have been extensively used and advised as specifics has not been such as to substantiate the claims made for them by their authors.

Osler says, on the subject of intestinal antiseptics: "Very laudable endeavors have been made in many quarters to introduce a method of treatment directed towards the destruction of the bacilli, but so far without success. Good results have been claimed for the carabolic acid and iodine treatment. I can testify to their inefficiency."

Tyson says, on the same subject, in his Practice, page 46, that "the antiseptic treatment has not a truly rational basis, while the
extravagant claims of its advocates discredit their results."

Since it appears that the bacilli do not appear in the stools often until the end of the second week, and in no case before the seventh day, the antiseptic treatment pure and simple is a failure. All are agreed that the earlier the treatment is begun the better the results, and that the mortality is doubled after beginning treatment after the fifth day. To check bacterial activity as aimed at by the advocates of this plan would be a disastrous interference with the normal process in the bowels. No one has been foolish enough to claim that the so-called intestinal antiseptics can kill the pathogenic and spare the useful organisms.

This paper is written with no other object than to correct a wide-spread and generally misunderstood principle which often governs in the treatment of typhoid fever. It should be kept in mind that it is in its broadest sense a systemic affection, or "typho-toxin," and not a local disease.

FOUR FRACTURES TREATED BY OPERA-
TION AND WIRING BECAUSE OF
FAILURE TO REDUCE BY
CONSERVATIVE
METHODS.

By W. T. Sharpless, M.D.,
West Chester, Pa.

The following cases, which were met with in the wards of the Chester Hospital, at West Chester, Pa., seem to be of sufficient interest to be reported:

CASE I.—A. T., aged twenty-eight, butcher, admitted February 20, 1898. Dr. Elwood Patrick and myself found this patient in the ward when we came on duty April 1, having been in the hospital forty days. On February 18 he had jumped out of his wagon to stop the horse, and struck unexpectedly on the frozen ground. He heard a crack, saw blood coming out of his leg, and was unable to move. Two days later he was brought to the hospital and was found to have a compound comminuted fracture of both bones of the leg at about the middle. The wound was already seriously infected. He was etherized the day after admission, the wound cleaned out, the fragments brought into better apposition, and a wet antiseptic dressing applied, with the limb in a fracture box. It was in this position when he came under our care. He had no fever, his general condition was good, and the wound drained freely. There was no union.

Dr. Edward Martin being at the hospital at this time, he was asked to see the case and advised the following treatment, which was carried out April 8, 1898: Patient was etherized, and as there was much dead bone and fragmentary and badly shaped ends, the ends of the bones were sawed off sufficiently to get good, square apposition, and the tibia wired with silver wire. The fibula was not wired as the end seemed to be held in good position by the muscles, in which it was embedded. Through-and-through drainage was used, and a plaster cast was applied at the knee and one at the ankle, with firm splints between them, so arranged as to admit of free drainage and dressing. Three days after the operation the foot had swollen so much that the casts had to be removed, and the leg was placed in a fracture-box and dressed thrice daily. For some days there was a foul purulent discharge and some fever. These lessened, however, and finally ceased, and on June 9 a plaster cast was applied, trapped, so as to admit of dressing a small wound on the anterior surface of tibia. The rest of the wound had closed.

The case passed out of our care July 1. The records of the hospital show that the cast was removed July 13, when there was firm union, but a sinus leading down to dead bone. This was curetted July 18 and kept in a fracture-box until August 22, when the cast was reapplied and he was allowed to go on crutches. By September 20 he could walk with a cane. On November 9 the bone was again curetted, and some necrosed material removed. On November 25 sinuses had closed. He was discharged February 20 of this year, exactly a year from date of admission, with a small superficial wound on the tibia. He has been at work since. We hear he is driving an ambulance for a Philadelphia hospital.

CASE II.—G. E., aged forty-five; gas-fitter, admitted March 20, 1899. While at his work he fell from a step-ladder a distance of three feet, striking his knee against the floor. The knee being flexed, the weight was received upon the head of the tibia. He sustained a fracture of the femur immediately above the condyles, with some comminution of the fragments, which permitted of great mobility in all directions. The skin was not broken. Buck's extension apparatus with sand-bags was used. Great swelling of the thigh and knee-joint occurred, with much discoloration
—probably from hemorrhage from a large vessel. At first but small weight was used. This was subsequently increased in an effort to overcome the shortening, until 23 pounds was used. Even with this weight there was a shortening of about one and a half inches. The swelling disappeared in about a month. The leg was examined from time to time, but no union occurred.

On May 26, two months after the injury, there being no union, Dr. Edward Martin operated, making an incision on the outer side of the thigh above the knee seven inches in length. The lower fragment was tilted backward, and some muscle and fibrous tissue were between the fragments. There had been no attempt at repair. It was not found possible by flexion or any other manipulation to completely reduce the fracture until about an inch had been sawed from the lower end of the upper fragment. The ends were then brought into good position and wired. A cast was applied, which was removed June 25, 1899. The wound had healed perfectly. There was still some motion; a new cast was applied and the patient was allowed to get up on crutches.

Case III.—J. S., aged forty-one, farmer, admitted May 22, 1899. The day before admission, while leading a colt to pasture, he was thrown down, the left knee being twisted and thrown violently against a stump, producing a fracture of the left femur immediately above the knee—almost identical in character and position with Case 2. The fracture was oblique, and the lower end of the upper fragment had perforated the muscles at the side of the thigh and could be felt immediately under the skin. Before admission an attempt was made to reduce the fracture, which was unsuccessful, it being found impossible to get the point of the upper fragment out of the mass of muscles in which it was embedded. A similar unsuccessful attempt was made after admission to the hospital.

The case was operated upon by Dr. Martin one week after admission. It was found that infection of the wound had occurred, probably through the skin, and a considerable amount of pus was present. An incision was made on the outer side of the thigh and one on the inside. It was with a good deal of difficulty that reduction was accomplished. Some loose fragments were removed and the ends of the bones wired—the wires being passed through the ends of the bones and also wrapped around them. Gauze drainage was used, which has been renewed daily, and the wound irrigated with a bichloride solution. Casts were applied above and below the wound with strong splints between them. There has been a free purulent discharge in this case and regular hectic fever, and considerable failure in his general health. Within the past week, however, the fever has lessened, and as there seems to be some union we will persevere in the effort to save his leg.

Case IV.—J. B., aged twenty-eight, laborer, admitted June 8, 1899. A bank of earth and rock fell on him while working in a quarry, catching his legs especially, and causing a compound comminuted fracture of the left tibia and a simple fracture of the right fibula, both near the middle of the bones. Two and a half hours after the injury he was brought to the hospital and etherized. It was found that a small piece of bone nearly one inch long on its largest side was completely separated, also a few smaller chips, thus taking a piece completely out of the tibia, and leaving two oblique ends which overlapped about one inch. The fibula not being broken, shortening was prevented. The incision was enlarged along the inner side of the leg where the fragments protruded, and a counter-opening was made about four inches in length just external to the crest of the tibia, and the exposed bones drilled and wired. As it was found that this did not hold them firmly the wire was wrapped around the fragments. A drainage-tube was put through the leg and the whole placed in a fracture-box. This wound has suppurred but very little, and the temperature has remained nearly normal. At this writing the case bids fair to do well.

Spontaneous Escape through the Umbilicus of a Catheter Introduced into the Uterus.

By F. N. Eckman, M.D., Philadelphia.

On March 1 of this year I received a very urgent call to see Mrs. H., an old patient of mine, whom the messenger stated was dying. I was out at the time, and the call was referred to my friend and neighbor, Dr. T. O. Nock, who saw her and can confirm this rather remarkable story. The doctor reported to me when I saw him in the evening that the patient was seriously ill and advised me to see her early the next morning, which I did and found the following state of affairs:

The patient is twenty-five years old,
married, rather stout, weighing 200 pounds; she has had two children, the youngest twelve months, and one miscarriage. I found her lying on a lounge down-stairs partially dressed. She was very much thinner than when I had last seen her, and there was an anxious expression about her face that denoted extreme suffering. I obtained the following history, which was rather reluctantly given:

On February 13, having missed her period twenty days, she consulted a physician, who to help her out of her supposed trouble introduced a catheter into the cavity of her uterus and told her to return the following day to have it removed. This she was unable to do on account of the blizzard which occurred on that date. She suffered some pain and passed a few drops of blood by the vagina, but did not return to the doctor for three days. When she did return the doctor upon examination was unable to find the catheter and told her she had lost it, but that she was all right and need not worry. She went home much comforted, but suffered so much pain that she sent for her abortionist, and was treated by him for about two weeks for diarrheal pain and irritable bladder, with vomiting and great prostration. These symptoms the abortionist summed up to mean typhoid fever, and had given her up to die at the time I was sent for, which was fifteen days after the introduction of the catheter.

Examination showed a fiery red tongue, a weak, rapid, thready pulse, great abdominal distention and tenderness. On palpation of the abdomen a distinct mass, which was more tender than the rest of the abdomen, was felt a little below and to the right of the umbilicus, about the size of a three-months pregnancy. On account of fat and extreme tenderness it was impossible to make a thorough bimanual vaginal examination, so that all I could make out was that this mass seemed to be continuous with the uterus, which was so drawn up and firmly fixed that it was almost impossible to reach the cervix. What this mass was I could not determine, but as it might be any one of a number of things which demanded surgical interference I advised her removal to a hospital with this end in view. This was most emphatically declined by the patient, as also was the proposition to have a surgeon see her, and I agreed to treat her expectantly, but offered very little encouragement for her recovery. I consented to the plan the more readily because the case seemed a very unpromising one for operation.

To my surprise she began to improve after a few days of symptomatic and tonic treatment, so that her diarrhea and vesical tenesmus passed off, and at the end of two weeks it was impossible to feel the mass by external palpation, while by the vagina the uterus had descended to its normal position, and the mass, which still seemed a part of it, was smaller and more posterior in position. She was at this time able to take a little food, and opiates were suspended. I did not see her again until April 1, one month after I was first called. At this time she sent for me on account of an inflamed and tender navel. This she was poulticing and said it was causing her much suffering. It was a most curious looking thing, a glistening hard white nodule about the size of a silver quarter as the center, around which radiated four or five other oblong nodules of a similar character. I ordered an evaporating lotion, and considered it the strangest thing I had ever encountered. Five days later the central nodule, which continued to be very painful, began to take on a bluish tint and ruptured in another day or two, discharging a few drops of thin, offensive pus. Attempts to probe the opening were futile, the probe only entering about a quarter of an inch from the surface, where it was arrested by a resisting substance which felt not unlike cartilage. I left directions for antiseptic washings and a powder, and did not see the case again until April 11, when the husband came to see me in the evening and asked if I would stop the next day, as there was something black sticking out of his wife's navel which he said looked like a licorice lozenge. I was interested at once and proposed to go that night, which I did, and was able, with little difficulty while the patient sat up in her chair, to extract a full-length No. 9 linen catheter with the enamel dissolved off, together with a small quantity of foul-smelling pus.

The subsequent history is soon told. The sinus healed in a few days and the patient began to take on flesh, so that now she is up to her usual weight and has no abdominal symptoms.

I have never been able to entirely satisfy myself as to the route the catheter took, but I am of the opinion that the mass I felt was the uterus itself stretched by the pressure of the curled-up instrument inside, and that this stretching brought the fundus in contact with the abdominal parieties, so that when the uterine wall perforated, which it did about the time of my second examination, it
was surrounded by an inflammatory barrier which protected the peritoneal cavity. The perforation of the uterus allowed it to sink down again to its normal or nearly normal position, relieved the tension and the pain, and caused the disappearance of the mass from above.

The interesting features of the case are the total absence of any uterine discharge, the fact that she came down-stairs every day in spite of my injunctions to the contrary, as well, of course, as the fact that the woman is alive at all.

Of the lessons which this case teaches perhaps the two most important to the abortionist are: don't leave a catheter in the uterus without tying a string to it, and don't diagnose typhoid fever until the catheter has been found. The accident is not one likely to occur to honest men.

I do not claim any credit for the happy result, since I never considered that I knew what ailed my patient until the eye of the catheter presented in the wound.

624 Twenty-second Street.

**ON THE CHOICE OF OPERATION FOR STONE.**

**By John H. Brinton, M.D.,**

Professor of the Practice of Surgery and Clinical Surgery in the Jefferson Medical College of Philadelphia.

**LITHOLAPAXY.**

Given a stone in the male bladder, how shall the man safest get rid of it? In past times the answer would have been, "If the stone be small or soft, or both, crush it; if hard or large, or both, remove it through the perineum by the single, median, or bilateral operation."

At the present time, and since the introduction of litholapaxy by Bigelow, and the resuscitation and improvement of the supra-pubic method, new elements both of safety and danger to the patient have been developed and recognized, which demand thoughtful consideration. A sound conclusion as to procedure cannot be jumped at; it can only be reached by carefully searching for, comparing, and weighing the merits and demerits of each method of operation. Some of the disadvantages, or possible sources of danger, have not, I think, been as yet dwelt upon, at all events sufficiently, and will therefore bear a closer investigation.

The factors which should in great part influence in the choice of procedure for the removal of a bladder stone would seem to be: (1) The character of the stone, whether it be hard or soft, small or large; (2) its duration, or length of domicile in the bladder; (3) the probable condition of the bladder, the ureters, and kidneys, the degree and character of the involvement of these organs, and the disturbance of their functions; (4) the age of the patient; (5) the gravity of the symptoms, and the amount of general constitutional disturbance; (6) the urgency of operation.

A just appreciation of the above conditions will, I think, go far to indicate the proper course and special procedure to be adopted in each individual case. In a general way it may be stated that the best solution of the vesical calculus problem will be the removal of the stone without incision of the bladder. To crush a stone and have it voided by the urethra spontaneously, or even instrumentally, would be an ideal operation, provided, in the first place, that no injury from bruising or overdistention of the bladder walls occur, nor serious and permanent ill effects be produced on the urethra and prostate gland. In the second place, the procedure should be thorough—that is, the entire amount of broken stone should come away, so that no fragments may remain to cause or keep up irritation, or to serve as the starting-point of fresh or larger concretions. In the old and now almost obsolete method of lithotripsy, which I have so often seen practiced by experienced hands, the calculus was first finely crushed—in fact pulverized—with the duck-bill crusher, and then spontaneously voided in the urine stream—"piddled away," to use the language of the day. This, however, probably only occurred where the stone was soft and relatively small, and where the crushing had been very thoroughly accomplished. Perhaps in most cases some larger or irregularly shaped fragments remained in the bladder, acting as sources of irritation or as the nuclei of future calculi. Although successful in exceptional instances, the operation was in the main not altogether to be relied upon; it was too uncertain and imperfect. Thus it has happened that with the advent of litholapaxy the older lithotripsy or lithotripsy ceased in great part to be practiced.

The idea of litholapaxy, the crushing and evacuation of the stone at a single sitting, took firm hold of the professional mind, and this operation has been largely resorted to. Much has been expected from it; its early
successes have been widely spread, perhaps magnified, and its failures minimized, or imperfectly reported and dwelt upon. To such an extent indeed has this been the case, that by the laity and general profession this method has been looked upon as almost devoid of dangers, and therefore of universal application. Nevertheless, among those who have practiced it most a feeling of uncertainty has gradually grown up. There has been no doubt that this method of Dr. Bigelow has been a great advance upon the older lithotry, and that in proper cases it should always be resorted to; yet not a few deaths have followed its use, and in other instances complete evacuation of fragments has not been obtained, and repeated operations have been necessitated. These facts have since strongly impressed themselves upon the mind of the writer, who in consequence made a series of experiments to determine if possible the bearing and effect of each step of the procedure upon the final result; in fact, to analyze the method, and see where the fault, if any, lay, and how it could best be avoided.

The operation of litholapaxy, as is well known, consists of two parts or steps. The first is the crushing of the stone into fragments sufficiently small to pass through cannule or tubes introduced through the urethra into the bladder. These, like catheters and bougies, are of various sizes, the ends being bent into short curves, or else straight. The size employed is the largest the urethra will admit, the meatus having first been incised, if necessary.

The second step is the evacuation of the crushed fragments. This is accomplished by means of a rubber bulb filled with water, which is fitted to the mouth of the evacuating tube already inserted through the urethra into the bladder. The jet of water into the bladder, by sharp pressure of the bulb, produces upward agitation of the fragments of stone, and on each dilatation of the bulb—its diastole as it were—a suction effect results by which the fragments are drawn into a receiver attached to the rubber bulb, and so guarded that their reentry into the bladder cannot occur. If the calculus has been broken into fragments of proper size, these can be thoroughly evacuated by prolonged and careful continuance of these sucking or pumping efforts of the bulb. From a purely mechanical point of view this procedure seems almost absolutely perfect. But when applied to a vital organ, as the bladder, a delicate structure, and endowed with exquisite sensibility, it has often been noticed that its effects seemed out of all proportion to the amount of force apparently employed. Death has not infrequently resulted, and varying degrees of shock referred to idiosyncrasies, or simply not to be explained.

In the researches above referred to I sought to study the character and degree of force exerted by the rubber evacuator when sharply compressed. My object was to learn whether any real violence, or possible traumatism, might be unwittingly produced. The rubber bulbs employed were of varying degrees of purity; those of greater purity were softer and more readily compressible, and consequently a greater amount of water was thrown forward at each forced contraction of the bulb under hand pressure, averaging from two to two and a half ounces, or even more. With a bulb of harder or more adulterated rubber (for the india-rubber of the market is composed largely of whiting, with a small percentage of Para rubber or gum) the fluid ejected was about one or one and a half ounces.

The effect of throwing a small quantity of water into a bladder already filled, or nearly so, was most marked. Even with the most gentle digital pressure on the bulb the bladder became tightly distended, puffed around the openings of the ureters; and if the pressure was continued or increased, it was exceedingly apt to burst.

In a recent demonstration before the Academy of Surgery of Philadelphia the bladder from the pig under a very moderate bulb pressure ruptured, evacuating its contents. Clinically I have observed that an anesthetized patient will often groan when the distention, or rather overdistension, of the bladder is produced. This is a symptom which I dread, as indicative of overdistention, and prophetic of shock and disastrous consequences.

The result of these cadaveric researches has convinced me that an excessive distension of the bladder, amounting to overdistention, may easily be unwittingly brought about even by the hands of a conscientious and careful surgeon. I believe, too, that to this cause, more than to any other, must be attributed the occurrence of a degree of shock, which sometimes is followed by fatal results, and which we have perhaps attributed to idiosyncrasies, alcoholism, or depraved conditions of the system.
It would indeed seem that safety in litholapaxy can only be insured by the surgeon constantly remembering the peril to the patient resulting from sudden surgical and mechanical overdistention of the bladder. Bearing this in mind, it would be well to adopt some such rule as this: Never to perform any of the steps and manipulations of litholapaxy, either those of crushing or of evacuation, and especially the latter, in a bladder which contains more fluid than three-fourths of its measured capacity. Thus, if under ether the bladder capacity be found to be ten ounces, after emptying it by a catheter inject into it 7 to 7 1/2 ounces. This will leave unoccupied a vesical space which will permit increased extension to the extent of the entire capacity, represented by about two and a half ounces of fluid, that being about the amount of the fluid forced inward by moderate digital pressure on the bulb. It is to be remarked that during all this manipulation there is some backward leakage through the urethra from the bladder. This is gradual, and while it lessens the general vesical contents, preserves as it were the normal mean between injection and ejection, but is not sufficient to relieve a sudden overdistention or to avert its evil results.

Holding these views, I believe that before undertaking the operation of litholapaxy, it is important, indeed essential to the safety of the patient, accurately to determine the capacity of his bladder. This should be done three or four days before the proposed operation by first drawing off all urine with a catheter, and then distending the bladder to its full capacity by the flow from a fountain syringe under ordinary hydraulic pressure. The injected fluid should be mild and antiseptic—a weak solution of borax or boric acid. This injection should be repeated when the patient is first anesthetized at the time of operation, when a large vesical capacity will probably be obtained. The capacity of the bladder in ordinary conditions, and when dilated to its fullest extent under an anesthetic, is thus ascertained, and should be constantly borne in mind in the after procedure.

The first step of the operation is that of properly breaking or crushing the stone. It is not necessary, as in the old operation of lithotripsy or lithotrity, to pulverize the stone; it is sufficient to break it into fragments small enough to pass through the evacuating tube, under the suction efforts, which act whether the fragment be regular or irregular in shape.

In sounding for stone it is well to examine the bladder systematically, the amount of water being about half of its previously determined capacity. The same maneuver can be practiced with the crushing instrument as with the sound. The formula of examination of the late illustrious surgeon, Joseph Pancoast, I have found the most convenient and certain. According to his method the left side of the bladder is first examined with the point of the instrument directed upward, its convexity resting lightly on the posterior vesical wall. The handle of the instrument should then be depressed between the legs of the patient, and turned to the right a full circle, so that the beak shall pass lightly over the mucous membrane, behind the urethral opening, and therefore behind any projecting bar caused by prostatic enlargement, should such exist. Not infrequently calculi of small size may be found here, whose existence has previously been scarcely suspected. This is apt to occur in the bladders of old men when posterior enlargement of the prostate has taken place, with phosphatic or decomposing urine. The instrument should then be carried backward, point upward, on the right side of the bladder, to examine the right side. It may then be withdrawn, point upward, in a median line, sweeping the upper wall of the bladder by successive semicircular movements.

The mucous surface of the bladder may thus be gone over in its entirety, and a stone if present will probably be detected. If not found, probably none exists. In any event the operator will have the comfortable feeling that his examination has been made systematically and with a degree of surgical precision. In instances where the results of this examination are negative, or where the calculus previously recognized cannot be again detected or grasped, it is well to reexamine by first decreasing and then increasing the amount of fluid in the bladder. It is well also to remember that when the fluid contents are largely increased the stone may at times escape observation. It is, as it were, drowned by the amount of fluid, and its presence may be undiscovered from the very extent of mucous surface to be investigated with the sound. So also when there is too little water in the bladder, a calculus, especially if small, may be covered up by mucous folds, or hidden behind a prostatic bar.

It is not uncommon to see vertical up and down movements of the sound made by some surgeons in sounding a bladder for stone.
This is a sort of "prodding" hurtful to the bladder walls. Its only warranty is in some cases to estimate the size of a stone already located. It surely is better in dealing with the lining of a tender bladder to avoid all disturbing or rough manipulation. When the stone has been felt, it should be caught in the crushing instrument as quickly as possible. This may be done most easily by letting the convexity of the crusher settle or rest lightly on the mucous membrane of the base of the bladder by the side of the stone; then on separating the blades, and tapping gently the handle of the instrument while the blades are turned towards the stone, the latter will fall into the grasp of the crusher. The blades with the stone are then slightly raised from the bladder wall and the screw turned until the stone is broken. This process can then be repeated on the fragments. One objection to the old form of lithotrites, even when fenestrated, was their liability to nip and cut or tear the mucous folds, and even to become impacted. When not fenestrated they were very apt to become impacted by fragments, so that their withdrawal was difficult and dangerous. The writer has known death to result from this cause in two instances. In one the urethra was torn off at the bulbomembranous region, and in the other death followed from postoperative sloughing of the urethra. The modern crusher of Bigelow, with its beaked male blade, and those of Thompson, Keyes, and Forbes, seem to be free from all mechanical objections and are sufficiently powerful to crush any stone which it may be desirable to attack, and in all of these the blades are so arranged as completely to obviate all danger of impaction and hindrance in withdrawal.

In using the evacuating bulb, so as to suck out the fragments of calculus into the attached receiver, it is desirable that the pressure of the bulb should be made quickly and sharply, and be uniform. The water in the bladder should not be allowed to escape by the side of the cannula to such an extent as to hinder the agitation of the fragments necessary to their passage into the opening at the end of the tube. This suction can be best obtained when the bladder is filled to one-half or two-thirds of its capacity, and the operator should see that this relative degree of fulness be preserved; otherwise it may easily happen, during the continuance of a prolonged operation, that the vesical contents may be unduly lessened by constant urethral dribbling without attracting the attention of the operator. The surgical manipulations may be thus so protracted as to lead to inefficient or perhaps unsatisfactory results.

The great desideratum in litholapaxy is the removal of the stone to the last fragment. Nothing should be left to serve as the nucleus of a fresh calculus. Repeated trials, with a well filled and with a largely emptied cadaveric bladder, have convinced me that the last fragments are with difficulty gotten away, if the viscus be nearly emptied, and that the best chance for their withdrawal is when the bladder is distented to one-half or two-thirds of its fluid capacity, as above stated. As to the special evacuator, that is simply a matter of personal preference. The Bigelow instrument in its later varieties, that of Dr. Otis, or one of the modified Thompson instruments, will answer equally well. The essential matter in the employment of each is that the operator should be perfectly familiar with its use, and be able to gauge accurately the amount of water ejected and withdrawn at each forced systole and diastole of the bulb. Some little care is necessary in filling the apparatus with water to exclude the air as nearly as possible. This can be best done by immersing the whole apparatus sideways in a tin box, about five inches deep, filled with the antiseptic fluid preferred.

The litholapaxy of the books is usually regarded as a procedure of little gravity, and one which the general surgeon can readily and safely do. This I do not think is quite the case. It really is a most delicate operation, requiring for its performance a high degree of skill and frequent practice. I think, moreover, that the dangers which may result from sudden and violent overdistention have been largely overlooked, or if recognized have not been fully estimated.

The advantages of litholapaxy when carefully used in appropriate cases, when the bladder walls are fairly healthy, are:

1. The evacuation of the stone at a single sitting.
2. The completion of the operation to the last fragment.
3. The absence of traumatism and violence when skillfully practiced.
4. The rapid convalescence of the patient, and his ability to resume his ordinary avocations in four or five days.

The disadvantages may be appreciated by remembering that:

1. The operation is one of several stages or steps dependent on each other, a perfect
performance of all being essential to ultimate success.

2. The risk from sudden excessive distention of the bladder, with the attendant possibilities of severe shock and perhaps of death.

3. The difficulty of removing all stone fragments, and the doubt as to its accomplishment. The outcome of the operation must always be for some time uncertain, with the contingency of renewed symptoms and further surgical interference.

4. The difficulty, amounting almost to impossibility, of detecting, grasping, and crushing small calculi hidden behind a backward projecting prostatic bar, or pouching in any mucous crypt.

5. Ignorance of the exact condition of the posterior prostate in old men, and of growths invading the bladder walls, despite the aid of the cystoscope and of the x-rays.

(To be continued.)

ON THE METHOD OF OPERATING FOR UMBILICAL HERNIA, WHETHER FOR RADICAL CURE OR WHEN STRANGULATION HAS OCCURRED.

Marsh (British Medical Journal, June 17, 1899), after describing the method of radical cure for umbilical hernia in common use, expresses his conviction that this proceeding may be altered in two particulars, with the result that it occupies less time, is more easy, and, as experience shows, safer for the patient.

The first point concerns the treatment of the sac; the second the management of the adherent omentum. As to the sac; as a first step (originally suggested by Mr. Treves) this is stripped entirely of all the surrounding tissues and completely isolated down to the opening through which it leaves the abdomen—that is, to the level of the linea alba.

The isolation of the sac is thus effected. A curved incision starting from the middle line above is carried over the right side of the swelling to the middle line below, and a similar incision is made on the left side, the two together forming an elliptical wound. These two incisions are so planned that they include the skin which covers all the front of the swelling, only enough being left to allow of the closure of the wound, without tension, in the middle line, when the hernia shall have been reduced and the sac removed. Next, the whole thickness of the subcutaneous fat is separated on either side from the outer surface of the sac, including its neck. This is easily carried out by a sweep of the finger and a few touches of the knife.

The operator now has the hernial sac and its contents clearly defined and under control. The sac is opened by an incision in the middle line long enough to afford free access to its interior. The omentum—any part of which not in the neighborhood of the neck of the sac may be freely divided, provided it has been first tied or securely clamped above and below—is unfolded and the intestine exposed. This, when such adhesions as tether it within the sac have been divided, is returned. In cases in which extensive and firm adhesions have formed between the intestine and the omentum of the sac, it is safer and quicker to cut through these structures at a little distance from the gut, so that portions are left adherent to it, than to persist in dissecting them off. The intestine having been returned into the abdominal cavity, the omentum is taken in hand.

In dealing with this structure, the usual method is to detach it at what may be termed its periphery from the sac wherever it is adherent. This, if the hernia is large and the adhesions are extensive, is a tedious proceeding which occupies considerable time. The following is a more expeditious method: The operator makes his way to the omentum where its neck emerges from the abdomen. This neck or stem he defines and isolates so that he can pass his finger completely around it. If it is adherent to the ring the adhesions must be separated. The stem is now tied in straps in the usual way, divided beyond the ligatures, and returned into the abdomen. There will now remain the sac, containing, perhaps, a large mass of more or less adherent omentum. The sac is cut away by dividing its neck at the level of the ring. Its edges are brought together with sutures, and the peritoneal cavity is thus closed. The ring itself is next obliterated by strong buried sutures, and the external wound is closed.

Marsh states that during the last three years he has performed the operation he has endeavored to describe nine times—four times for radical cure, and five times for the relief of strangulation. All the patients recovered. Two patients, in whom strangulation had existed for three and four days respectively, were in a grave condition for the first twenty four hours. The remainder bore the operation well, and gave no anxiety from the first.

THE TREATMENT OF CHRONIC DIARRHEA.

The condition of chronic diarrhea is one which is frequently met with at the present
time, although it is not so common as it was
some years since, when the survivors of the
civil war were more numerous. Even to-day
patients present themselves to the physician
with the statement that they have suffered
from this condition ever since the days of
their army life, and often it is surprising that
their general nutrition is so little impaired.

On the other hand, we meet with patients who
have fewer or less copious stools, who never-
theless lose flesh with great rapidity and be-
come much emaciated. In such cases the
underlying condition causing the affection is
probably situated high up in the bowel, where
it prevents the proper digestion and absorp-
tion of food, or where by causing too active
peristalsis it causes the food to be hurried
down to the lower bowel before absorption
can occur. In the cases where great emaciation
does not take place the lesions are situ-
ated, it may be, in the lower bowel, and there-
fore do not deprive the patient of food.

Nevertheless, it must not be forgotten that
in some instances lesions situated in the lower
bowel reflexly cause excessive peristalsis and
consequently diarrhea, and of these lesions
fissure of the anus is perhaps the most com-
mon. In rare instances reflex diarrhea arises
from irritation produced by disease or dis-
order of other pelvic organs, and particularly
is this true in women.

Cases of the character just referred to are
often very puzzling when we attempt to dis-
cover their cause, and often go from one
physician to another in the endeavor to find
the remedy for their ailment.

Another class of cases is that in which the
diarrhea depends upon actual catarrhal or
ulcerative changes in the intestinal walls. In
very few instances is this ulceration in the
small bowel, except, perhaps, in cases of con-
valescence from typhoid fever when diarrhea
may be persistent. Even in such cases, how-
ever, the lesions may be in the colon rather
than in the ileum.

Finally, we find instances in which de-
cicient digestive activity permits changes to
take place in the food, and diarrhea results—
an effort on the part of nature to get rid of
useless and offensive materials.

As a result of this line of thought it is evi-
dent that before we attempt to treat a case
of chronic diarrhea, we must study its causative
factors and inquire into the minute de-
tails of the case before we can prescribe for
it intelligently. Very often the employment
of the ordinary formulae useful in acute diar-
rhoea gives temporary relief, but finally fails,
because it simply checks peristalsis and does
not remove the cause of the complaint. Thus
in one instance, recently seen, the constant
use of a flannel binder about the abdomen
entirely cured an obstinate diarrhea which
had continually recurred, and which was evi-
dently dependent upon the chilling of the
abdominal wall with consequent congestion
of the intestines. Such a state is very com-
monly met with in young children, whose
legs are often improperly clad even in cold
weather, and in persons who continually go
about with wet feet. Therefore proper cloth-
ing and careful methods of life are absolutely
necessary for recovery.

Again, there is no doubt that the diet of
such patients receives too little attention in
many instances, and, a careful study of the
ordinary diet of a given case may reveal
some article evidently at fault, the prohibi-
tion of which is followed by cure. In close
connection with this subject is that of drink.
Many cases of morning diarrhea are distinctly modified if the patient steadfastly refrains from drinking much liquid the evening before. This is probably due to the fact that the presence of much fluid in the upper bowel causes excessive peristalsis during the night, and this fills the lower bowel with fluid before enough can be absorbed to cause the contents of the colon to possess the proper consistency. Further, this lack of absorption of fluid causes thirst, and this again provokes excessive drinking of fluid.

Finally, a word or two as to medicinal treatment. In many cases in which the fault lies in faulty digestion, the administration of some active digestant is advisable. If the nutritious foods seem especially prone to cause the disorder, the use of a liquid preparation of pepsin with hydrochloric acid may be a wise procedure, such as:

\[\text{Pepsin cordial, } 1 \, \text{fl oz};\]
\[\text{Acid hydrochloric dil., 1} \, \text{fl oz or } 1 \, \text{fl oz};\]
\[\text{Aquae dest., q. s. } 1 \, \text{fl oz}.\]

\textbf{M. Sig.}: Two teaspoonfuls after meals.

Or if an astringent seems advisable dilute nitric acid may be substituted; or again, if the liver seems torpid fresh nitrohydrochloric acid will be better. Sometimes where a marked astringent is needed, aromatic sulphuric acid is better still.

If the diarrhea be one of fermentation and indigestion the following may be useful:

\[\text{Taka-diastase, gr. xv;} \]
\[\text{Carbo ligni, gr. xv;} \]
\[\text{Pancreatin, gr. xv.}\]

\textbf{M. Ft. in chart vel capsule No. xx.}

If fermentation is particularly marked, salol may be added for its antiseptic effect.

If the diarrhea is due to lesions of the lower bowel, local applications are needed, and medicine by the mouth is comparatively useless. In such instances high and gently given colon injections of water, cool if fever is present, or sulphocarbolic of zinc twenty grains in each quart of water, may be useful. Sometimes an idoform suppository containing five to ten grains of this drug will, by acting as a local sedative and alterative, do much good.

---

\textbf{THE RELATION OF MOSQUITOES TO MALARIAL DISEASE, AND THE VALUE OF CERTAIN SUBSTANCES IN THEIR DESTRUCTION.}

It may be of interest in connection with the paper which is published in the current issue of the \textit{Therapeutic Gazette}, detailing the experiments which have been made by Celli and Casagrandi in Rome upon the various substances which will destroy, or rather prevent the development of, the mosquito, to review certain facts bearing upon this theme.

To those who have not kept themselves in touch with the recent experimental work upon the ability of the mosquito to act as the inoculating agent of malarial infection, it may not seem that Celli’s experiments are particularly valuable—over and above the relief which they may give from the annoyance due to mosquito bites—but as soon as one makes himself acquainted with these investigations and finds that the mosquito in certain of its varieties is fully responsible for the severer forms of malarial fever, these investigations in the line of preventive therapeutics become extraordinarily valuable.

It will be remembered that a number of years ago Sergeant Major Ross, of the English Indian Medical Service, reported certain extraordinary results found by him in the study of the \textit{Proteusoma labbd}, which is one of the malarial parasites found in the blood of birds. His studies were chiefly connected with the observation of these parasites in gray mosquitoes, and he found that mosquitoes were the means by which malaria of the avian type was conveyed from one bird to another.

These investigations led Manson to advance the hypothesis that human malaria was due to this cause. And the next step of any great importance was the observation of MacCallum of another form of malarial parasite infecting birds, viz., the \textit{Halteridium labbd}. This investigator showed beyond all doubt that the flagella derived from this parasite—and it is well known that similar flagella are given off by the parasites of human malaria—represent sexual elements. He found that there were two forms of halteridium, one hyaline in character and the other granular. It is the hyaline form which undergoes flagellation; the granular form never undergoes this change. The process carried out is as follows: The flagellum, tearing itself loose from the hyaline form, approaches and penetrates the granular form, and from this union, or fertilized parasite, an actively moving organism develops. While MacCallum’s observations only dealt with the parasite of birds, Bastianelli and Bignami, two Italian investigators, have found that there are two forms of the tertian parasite of man.
as well. The male form they call "Microgametes," the female form "Macrogameti." The nucleus of the male form is small and centrally situated, and that of the female is situated at the periphery and is larger.

These observations have also been still further confirmed by the fact that after MacCallum had observed these conditions in the blood of birds, he also saw the same process of fertilization take place in the blood of a woman who was suffering from estivo-autumnal fever.

Major Ross, in 1897, found certain peculiar pigmented cells in the stomach wall of two mosquitoes fed on the blood of a patient suffering from estivo-autumnal fever, and furthermore he found that these cells were only found in mosquitoes which had been fed upon the blood of patients so infected. Ross has also shown that these reproduced bodies accumulate in a small gland situated near the proboscis of the mosquito, and it is believed that when the mosquito bites an individual, the individual is thereby inoculated with the malarial parasite, which rapidly develops in his blood.

Convincing evidence of this has been advanced by Grassi, who found that three varieties of mosquitoes are constantly present in malarious districts and absent in districts where this disease is unknown; and further, that one of them, the Anopheles claviger, is found in districts where tertian malaria is present, whereas the other two forms, viz., Culex pennisularis and Culex malaria, are invariably found in those localities and at those places where the estivo-autumnal fevers are present.

Further, Grassi has taken mosquitoes from malarious districts and allowed them to bite individuals who have never had malaria, and produced malarial fever in these individuals. This experiment has been verified by other observers.

Much of this information is derived from the article of Dr. W. S. Thayer in Progressive Medicine, and that of Dr. Futercher in the American Journal of the Medical Sciences for September, 1899, and also from an article recently published by Ross in the London Lancet. Taken in conjunction with the studies published in this issue of the Gazette they show clearly the interesting and valuable results of an original research in which investigators from all parts of the world have given their best efforts for the relief of a common malady.

THE BUILDING OF A NOSE UPON A METALLIC BASE.

Though there have been many cases reported in the journals, and often with convincing illustrations, showing that defects of the nose or the almost complete destruction of this organ may be remedied by the building up—by transplanting flaps—of a new nose upon a framework of celluloid, platinum, or other smooth rigid material, the profession has not been enlightened as to the ultimate results of such operations.

To the surgeon it seems obvious that in many of these cases there would ultimately result either persistent suppuration or exposure of the foreign body by perforating ulceration of the transplanted flaps, or necrosis of the bones upon which the bridge is supported.

Martin (Revue de Chirurgie, No. 8, 1899), who warmly advocates this method, states that this ulceration is generally due to the fact that the flaps taken for the formation of the new nose are insufficient. As a proof of this he publishes two photographs—one of his patient taken immediately after the operation in 1878, and exhibiting a nose apparently afflicted with elephantiasis; the other taken in 1888, showing a nose of almost normal size, and if not beautiful, certainly much better than the total or partial absence of this organ.

The base of support, not necessarily bone, should be large and should not be subject to any great pressure. The formation of this base of support is accomplished by an ingenious method, fully described and illustrated by Martin.

Martin acknowledges that the scaffolding upon which the nose is built may be displaced and be subject to constant motion by the contraction of the face muscles. This, he maintains, can be prevented by firm fixation; indeed, he holds that all accidents incident to this method of rhinoplasty are easily avoided. He quotes a case operated on by Bonet in 1885 in which the result is as admirable to-day as it was a few months after the operation. It is, however, suggestive that these two cases are the only successful ones cited in the article, and that Martin elaborated his method and published it in 1889.

It is to be hoped that the ultimate results of these operations, which have certainly been performed by the hundreds, may be published; since thus we may learn to judge truly of the value of the method, and in case
it is only exceptionally successful, patients may be spared a procedure not free from pain or even danger, and which affords but a slight prospect of a cure.

AMPUTATION THROUGH THE HIP-JOINT.

This operation, at one time regarded as among the most formidable in surgery and presenting a mortality so high that few surgeons either advised or performed it, has, with the improvement of technique and the fuller recognition of the means by which surgical shock can be prevented and treated, been followed by such admirable results and been so generally practiced when the indications for its performance are present, that it has to a great extent ceased to be a prominent topic in current literature.

A historical account of the development of the operation, such as is given by Levison in the Journal of the American Medical Association of June 24, 1899, in relation to two successful operations of this nature, both performed on the same morning, is of very great interest. He recalls the fact that this operation was not performed until the end of the eighteenth century, when Larrey, the then master of his art, of seven such operations lost all his cases. Blandin, however, in 1794 saved one of three cases.

The first successful American operation is accredited to Brashear, a Kentuckian, in 1806. The appalling mortality shown in Ashhurst's tabulation of 633 cases, over sixty-four per cent, applies to the preantiseptic period, during which time there was no considerable advance in technique made.

The suggestions of Woodbury, to compress the common iliac artery with the fist inserted in the bowl; of Davy, who advocated the use of a lever; of Jordan-Lloyd, who used a rubber bandage; of Trendelenburg, who advocated the use of a steel needle and rubber ligature; of Thomas, who practiced subcutaneous ligature; of Macwen, who compressed the abdominal aorta beneath the umbilicus, by means of the fist applied against the vertebral column through the abdominal wall; and of other ingenious surgeons, are mentioned and described, including McBurney's method of direct intra-abdominal finger compression of the common iliac artery, practiced by incising the abdominal wall as in appendix operations. The finger is introduced through the incision and compression made.

Wyeth's modification of the Trendelenburg method was practiced and is advocated by Levison, and, indeed, it is commonly accepted as the most serviceable by the profession. This method has reduced the mortality from sixty-four to sixteen per cent, as shown by sixty-nine cases tabulated by Wyeth.

Erdman states that from 1884 to 1894 there were eighteen hip-joint operations done in the New York hospitals, with eight deaths. Of these, but seven were done by the Wyeth method, and all recovered, leaving eight fatal cases out of eleven done by other methods.

Levison has collected twenty-eight cases since Wyeth's statistics were published, dating from 1896, with three deaths, giving a mortality of 10.7 per cent.

Levison firmly believes that the mortality of the cases collected by him since 1896, since which time hypodermoclysis has been generally resorted to, shows that this precaution accounts for the diminished death-rate.

Furneaux Jordan's method, practiced mainly in England, has been modified by Wyeth in such wise that the stump is shorter, the section through the muscles being made at the level of the trochanter minor.

It is probable that the comparatively meager number of reports found in current literature, forming in a way an insufficient basis for study and particularly for tabulation and computation of mortality, is due to the fact that this operation is no longer unusual, and that recovery is the rule rather than the exception. The need for hypodermoclysis is the exception rather than the rule, since when the operation is performed with any degree of skill it is practically bloodless and the shock is consequently a minor factor. When performed for the removal of crushed and lacerated limbs, the immediate mortality will still be high, since the fatal injury has usually been inflicted before the surgical operation is performed. Under these circumstances hypodermoclysis and the modern treatment for shock may be life-saving. A convincing statistical evidence to this effect would be most valuable.

Reports on Therapeutic Progress

THE ETIOLOGY AND TREATMENT OF IRRITIS

Mr. John Griffith writes on this topic in Treatment for June, 1899. He thinks that local treatment deserves the first thought. Mydriasis is produced by the instillation of a
one-per-cent solution of sulphate of atropine. The value of atropine is not merely to prevent adhesions of the iris to the capsule of the lens, though this is of paramount importance, but also, by paralyzing the ciliary muscle as well as the sphincter pupillae, to secure complete intra-ocular rest—i.e., to suspend for a time all muscular movement within the eye, this to obtain physiological rest, the first and highest aim in the treatment of all acute inflammations. It is sometimes desirable to atropinize the second eye as well, even though not inflamed; by doing so, reading or using the sound eye for near work is successfully prevented. Atropine has still other advantages: it is an antiphlogistic; it reduces the amount of exudation and promotes absorption; it acts also as a local sedative. It is without doubt the drug par excellence for iridocyclitis. How much cocaine augments its action it is difficult to estimate; perhaps it does assist its sedative action to a slight extent. Besides the use of atropine, further local treatment is necessary. The eye should be protected from the light either by means of a broad shade, by the wearing of tinted goggles, or by the patient being kept quiet in a darkened room. In the worst cases, when the inflammation is most acute and the conjunctiva chemosed, absolute rest in bed is most essential. Local depletion by the application of leeches to the temple gives almost immediate relief, which is usually permanent. No drug can ease the pain so soon nor so effectually. The use of Heurteloup's artificial leech is better than no bloodletting, but cannot in point of efficacy be compared to the natural leech.

Hot applications to the eye are also very serviceable, especially in the rheumatic variety. The heat may be applied moist or dry. The dry pads may be kept on for some time without changing, but the fomentations should be repeated every half-hour.

Local treatment varies very slightly whatever the cause may be; there is, however, a point to bear in mind, and that is the occasional idiosyncrasy a patient has with regard to atropine. Atropine will sometimes create a severe local inflammation of the skin and cellular tissue of the eyelids and cheek, accompanied very often with a papular rash. Even a single drop of a weak solution may cause it to appear, and unfortunately the other mydriatics may all act in a similar fashion. The use of hydrobromate of scopolamine appears to be the least likely to be attended with such a consequence. Atropine poisoning in contradistinction to atropine irritation is less common, and the milder symptoms—dryness of throat, thirst, anorexia, sleeplessness, etc.—can usually be prevented by advising the patient to keep the lacrimal sac compressed for a few minutes after the drop has been instilled.

Before passing on to the treatment peculiar to the cause, there are a few facts to be borne in mind. At the commencement of every attack of iritis a free purge must be given overnight and a “black draught” in the morning. Alcohol should not be taken in any form, nor should smoking be allowed. Rest in bed should be determined by the severity of the case. In the slow chronic forms of serous iridocyclitis, which often run a course of six months or longer, it would be wrong to keep the patient a prisoner; he must have outdoor exercise, and it may be necessary to send him away to the seaside for a few weeks.

It is obvious that constitutional treatment plays an important part in cases of iritis due to gout, rheumatism, syphilis, diabetes, etc.

A patient suffering from gouty iritis requires his diet to be carefully regulated, to have his excretory organs properly attended to; and in that way to have his system cleansed. His bowels should be freely evacuated daily; he should be made to sweat freely either by injections of pilocarpine hypodermically, or by taking a Turkish bath twice or three times a week. These cases are also much benefited by leeching, and by the free administration of mercury.

In rheumatic iritis not dependent on gonorrhea, salicylate of sodium may prove of great service and may relieve the pain without the necessity of leeching, or even if the pain returns after the good effect of the leeches has passed off; but it cannot be relied upon. Iodide of potassium is another drug valued in the treatment of rheumatic iritis, even if it be of gonorrheal origin. It does not, however, give very striking results, and in anemic subjects may be not only useless, but actually harmful. Quite recently two cases of rheumatic iritis have come under Dr. Griffith’s care which he says were very obstinate indeed; no drug seemed to benefit them, and iodide of potassium certainly seemed to aggravate the condition. Upon giving strychnine the iritis in each case cleared up rapidly.

With regard to iritis caused by syphilis, there is little to write on constitutional treat-
ment. Mercury in some form or other is attended with the best results, and even if anemia be present—which is often dependent on the syphilitic virus—mercury should be persevered with. One of the worst cases of syphilitic iritis Dr. Griffith has ever witnessed, in which a large gummatous growth rapidly developed in the ciliary body, with ectasia of the sclera, yielded eventually to mercury. The patient was under the care of Mr. Juler, who pushed the mercury till its influence on the system was shown, and in spite of severe anemia the cure was marvelous. The inflammation and growth disappeared, and the anemia was also cured. Whether iodide of potassium by itself is of much service in iritis of syphilitic origin it is difficult to say, as mercury is usually combined with it; but mercury alone, or in combination with the iodide salts, is the best drug, and might safely be given in any case the cause of which is uncertain.

Diabetic iritis, like syphilitic iritis, is, contrary to what one would expect, very amenable to treatment. Besides the usual local remedies, codeine should be given internally and an antacidodylate diet taken. The exudation of lymph in the anterior chamber quickly melts away, and the eye returns to its healthy state.

One of the most interesting problems in ophthalmic surgery is the treatment of tuberculous iridocyclitis. The disease does not cause much if any pain until the advent of glaucoma. Glaucoma, moreover, does not develop in every case. There is iritis seen in some; in others there is very little visible inflammatory reaction. The growth gradually enlarges till the anterior chamber is for the most part filled, and then an evisceration of the sclera in the ciliary region appears. The question to be determined is how soon should excision be performed when the condition is recognized? And again, whether it is wisdom to excise the eye, as it may be regarded as a local deposit from some more gross tuberculous lesion in some remote part of the body, probably the lungs. It happens that in many instances no evidence of tuberculosis elsewhere can be discovered. Can this be the sole focus of the disease? If so, excision should without hesitation be adopted at the earliest possible date so as to remove the danger of dissemination. Dr. Griffith says the danger of dissemination seems to him to be in direct ratio to the tendency to caseation. In the eye tuberculous disease originates most frequently in the anterior part of the uveal tract; it is recognized, therefore, early, and excision is consequently resorted to long before caseation has taken place. This is fully proved on the examination of such eyes; it is very exceptional to find any caseating focus. Moreover, the danger of spreading to the other eye is remote indeed. He has never seen, read, nor heard of the second eye becoming tuberculous. In these two respects a tuberculous eye differs very materially from a tuberculous testis, hence it seems unnecessary to doubt the proper course to pursue. It seems to him that the eye should be excised at the earliest possible moment when any doubt as to the diagnosis has been sufficiently cleared up.

THE TREATMENT OF PRURITUS.

In treating pruritus it should be remembered that it may be both primary and secondary. In the primary cases it is simply due to some local irritation of the skin; in the secondary cases it arises from Bright's disease, jaundice, diabetes, acid dyspepsia, and similar conditions. Pruritus can also be divided into generalized itching and local itching. The generalized form often comes on periodically, and its onset is often produced by disturbances of the emotions, severe intellectual disturbances, marked alterations in diet, sudden variations in temperature, and particularly the development of heat of the skin when the patient gets into a warm bed after undressing in a cold room.

Besides these forms we also have that generalized form of pruritus which is seen in old persons, and apparently depends upon malnutrition of the skin and upon gouty tendencies.

In the way of localized pruritus we have that form which invades the neighborhood of the anus and is most frequently aroused at night, affecting often the coccyx and scrotum, and often aggravated by the presence of hemorrhoids.

In women we frequently have pruritus of the vulva produced by pregnancy, the menopause, and local irritation. Pruritus of the prepuce in males is often due to the passage of diabetic urine. Very rarely indeed pruritus of the palms and plantar surfaces is met with. This affection, although rare, is usually persistent.

In making a diagnosis of pruritus it must be remembered that anal pruritus may be due to the presence of seat-worms, and that itching of the skin in other portions of the...
body may be due to various parasites, such as pediculi and scabies.

The treatment of pruritus depends very much upon the condition which produces it. In cases of jaundice, the use of phosphate of soda and similar substances will often be advantageous. Dietetics will perhaps do the most good in cases of diabetic pruritus; taking care of the skin and the use of diuretic drugs may be of advantage in cases of renal disease. As a rule in diabetic cases, articles capable of undergoing fermentation in the alimentary canal should be avoided, particularly rich, greasy foods, and only small quantities of alcohol should be allowed, the patient living largely on green vegetables and roast and broiled meats. In many instances, particularly in those of gouty tendency, weak alkaline mineral water may be employed with advantage. Internally a prescription such as the following may be used to allay nervous irritation:

Valerianate of ammonia, 30 grains;  
Tincture of valerian, 2 drachms;  
Peppermint water, 3 ounces.

Two teaspoonfuls of this in a wineglassful of infusion of chamomile flower may be given three times a day.

In other instances where there seems to be intestinal fermentation a pill composed of carbolic acid 1 grain, extract of valerian 4 grains, given three times a day, may be useful.

Locally the treatment should consist in hot douches applied daily for the period of a minute, particularly over the vertebral column. In other instances full baths in which almond meal or starch-water has been added may be employed with advantage. In still other cases the addition of a quart of vinegar to the bath may be useful; and in still others the part may be locally enveloped in a cloth wet in an infusion of cocoa leaves in the strength of one-per-cent. In the way of sedative lotions the following may be employed:

Carbolic acid, 15 grains;  
Glycerin, 1 ounce;  
Water, 3 ounces.

Or,

Vinegar, 1 ounce;  
Hot water, 3 ounces.

Or,

Hydrate of chloral, 30 grains;  
Glycerin,  
Alcohol, of each 3 drachms;  
Water, 3 ounces.

In other cases hot water alone is of ad-
vantage, and finally may be used a lotion composed of

Corrosive sublimate, 2 grains;  
Alcohol,  
Cherry-laurel water, of each 1 drachm;  
Water, 3 ounces.

In the way of ointments the following are useful:

Menthol, 15 grains;  
Vaselin, 3 ounces;  
Carbolic acid, 15 grains;  
Oxide of zinc, 2 drachms.

Or,

Talc,  
Oxide of zinc, of each 1 drachm;  
Powdered camphor, 15 grains;  
Vaselin, 3 ounces.

In some cases a dusting powder may be useful, as for example:

Talc, 2 ounces;  
Subnitrate of bismuth, 2 ounces;  
Oxide of zinc, 1/4 ounce;  
Powdered camphor, 30 grains.

Orthoform has been employed in powder or ointment in some of these cases with temporary benefit, but it sometimes causes local irritation of the skin.

In some instances the application of the continuous galvanic current to the skin is of advantage, the positive pole being placed over the itching part and the negative pole at some distant point.

In very malignant cases good results have followed linear scarifications or the use of superficial cauterization with the thermo-cautery or with the electrocautery.

Of course, these methods are only useful in cases in which the affection is localized.—Journal des Praticiens, June, 1899.

CHRYSAROBIN A SPECIFIC FOR WARTS.

G. M. Fritz, in the Boston Medical and Surgical Journal of June 29, 1899, says that since 1895, when Dubreuilh called attention to the presence of warts on the feet, the characteristic differences between warts and corns have been more or less generally recognized. Warts on the feet are readily distinguished by their location (usually upon the planter aspect of the foot) and by their bleeding from a central, vertical bundle of papillie arranged like a pepper-box and ordinarily projecting somewhat above the pared surface. This central bundle of papillae is surrounded by a thickened area of skin penetrating to a greater or less depth and an outer painful zone of inflamed skin.
In 1891 Dr. Fitz saw for the first time a wart in this situation and attempted to cure it with salicylic acid in collodion. He found after a trial of three weeks that this was not effective. He was then led from its superficial resemblance to the lesion of psoriasis (bleeding points) to try a solution of chrysarobin in gutta-percha. The wart was thoroughly pared until there was profuse bleeding, and the solution applied to the denuded surface. The patient was directed to cut the surface every night and apply the chrysarobin. In a few days the pain disappeared, and the wart seemed diminished in size. In two weeks' time the wart was practically gone and the surface restored to its normal condition.

Since that time he has been able to apply chrysarobin in eight cases of warts similarly located. Some were apparently due to stone bruises; others to the irritation of defects in the boot; and of others, again, no history could be obtained. In one case there were three warts on the ball and two upon the heel of the same foot. Several of the cases came to him after having been treated for months by salicylic acid without success, even though the physician in charge had made the application himself each week.

In most cases the chrysarobin produced little effect before the end of the first week, except that the pain became less and the wart did not increase. In the second week change was rapid in most of the cases, although in a few cases there was still little effect. In the third week the majority were cured.

In the series of eight cases there have been no failures. Two apparent failures were traced to difficulty in paring the wart, and as soon as this was remedied by sandpapering the cure progressed favorably. On the whole, careful thinning of the surface with a sharp, fine glass-paper gives better results than paring with a knife, as the patient is less afraid of injuring himself and can more conveniently handle the paper.

Dr. Fitz's experience has been that chrysarobin may be applied either in a ten-per-cent solution of the ordinary gutta-percha solution or in a ten-per-cent ether solution. It is best to apply the chrysarobin at night, and to advise the patient to put on an old stocking, to prevent soiling the bedclothing. Application once a day in this way seemed ordinarily to be sufficient, but in obstinate cases it should be applied both night and morning.

The influence of the chrysarobin seems to be not only upon the keratinized portion of the skin, but also upon the proliferated blood-vessels in the papillary central part, for both disappear and true skin is formed over the surface. No scab was thrown off, but a considerable thickening of the surface was removed in each case by cutting and sandpapering.

A correspondent has reported two additional cases of cure with chrysarobin, making the total number of cases ten. The attempt to try the effect of chrysarobin on warts on other parts of the body has been possible in but one case (warts on the hand), where it had the same favorable effect.

Experiments with chrysarobin on corns show that it has practically no effect.

The claims of chrysarobin as a specific for warts may be summed up as follows:

1. Success in a series of ten cases of warts on the sole of the foot in which the diagnosis was perfectly clear.
2. Similar success in one case of warts on the hands.
3. No failure in any case where the application was made repeatedly on the denuded surface of the wart.
4. No subsequent recurrence of the wart.

---

TO HEAL VACCINATION SORES.

A. K. Bond writes in the Maryland Medical Journal of July 1, 1899, of his method of treating vaccination sores. He first points out that if the glycerinated virus proves satisfactory in its potency, and in its ability to keep its strength, as numerous competent observers claim that it does, the danger of accidental infections of the original inoculation scratch will be greatly reduced, especially if the scratching instrument is carefully disinfected by red heat or pure carbolic acid, if the skin is previously washed, if the virus is conscientiously made, and if the site of the vaccination is dressed aseptically until it is restored to its natural condition.

Practically, the physician has to dress many suppurating sores of vaccinations made by himself or by others.

The belief prevails in the community that a sore half an inch or more in diameter suppurating for weeks, or even for months, is an occasional sequel of successful vaccination which must be borne with patience, and is to be treated as well as may be with dressings of mild powders and salves of various sorts. The exposure of this error, Dr. Bond says, is his motive in writing the present article. He states that he knows by experience in their treatment that the most repulsive of such
sores may be caused to cease suppurating and to become a dry-scabbed sore in even a single painless dressing, and may be healed within perhaps a week. At first he supposed this fact was known to the mass of practitioners, but apparently it is not. The dressing referred to is a solution of nitrate of silver, about eighty grains to the ounce of distilled water. When such a sore is brought to him, he removes the scab if it has one, washes the surrounding skin clean, perhaps using alcohol, and mops the sore carefully with the silver solution until its surface is covered with a thick layer of white. When this has dried, a dressing of absorbent cotton with bismuth, or what not, dusted on it is applied. The pain of the silver in this strength is insignificant, the itching and irritation greatly diminish or disappear, the suppuration is permanently or for many days stopped, and the patient almost forgets the sore. In some cases the dressings begin after a week or more to become soaked with pus. A second nitrate of silver application may then complete the healing.

Dr. Bond says that before he learned this method of healing he used to consider post-vaccinia sores among the most disagreeable sores a physician has to deal with. Under dry dressing of bismuth, calomel, etc., they scabbed and suppurated off, and scabbed and suppurated, until both patient and doctor were tired and disgusted with them. Antiseptic ointments did cause scabbing but did not check suppuration. He finally tried nitrate of silver stick with great benefit, but timid children would never let him get near the sore a second time on account of the pain of the caustic stick. The eighty-grain solution is almost painless, yet very efficient; children seem not to dread its repetition. After the first dressing Dr. Bond has sometimes ordered a small quantity and directed the mother to make subsequent dressings with it until healing was accomplished.

Dr. Bond says he is encouraged to bring this very small therapeutic point to the attention of the profession by his knowledge of the fact (deduced from observation) that whenever smallpox threatens, and vaccination becomes general, there are in the community dozens, perhaps hundreds, of men, women, and children going about week after week with nasty sores which daily saturate the dressings and perhaps the clothing of the part with irritating pus, until the victims come to look upon vaccination as a very disagreeable ordeal to be avoided as long as possible in themselves, their children, and their friends, and welcome any statements, however ill-founded, that profess to prove that "vaccination is unnecessary and nearly as bad as smallpox." What wonder, if the patient has two or three months of discomfort whenever he submits to it? [This would not happen if good glycerinated vaccine was used.—Ed.]

Dr. Bond is accustomed at the time of vaccination to request his patients in case any pus discharge occurs to go to him at once, and to assure them that in a few days, perhaps in a single dressing, he will relieve them of all discomfort therefrom. He says the only reason he can suggest for the obstinacy of suppuration of these sores is that the sore was originally a pustule, and that when the top, or scab, comes off it leaves exposed at its site a pit walled and floored, not by healthy tissue, but by the bacteria-infected lining of the pustule. He cites the aphthous sore of the mouth as an analogy, where the floor of the vesicle is a tough nest of irritating materials, which, when cauterized away, layer after layer, leaves beneath a simple healthy wound. The granulations which spring up from the floor of the un-covered vaccination pustule seem to be very weak; hence the value of the mild caustic, whose stimulating and disinfecting powers act more deeply than simple surface washes or antiseptic salves.

Dr. Bond has reflected upon the question whether all vaccination vesicles ought not to be at once opened upon their appearance, and, by nitrate of silver or other like application to their interior, brought at once to abortion. This method has been adopted by some in smallpox eruption upon the face and hands. If the whole protective influence of vaccinia has been already received when the papule begins to swell into the vesicle, the prevention of the maturation of the vaccinia vesicle by any harmless measure would be a reasonable and desirable undertaking. It is possible, however, that substances absorbed from the vesicle intensify and complete the immunity, but he thinks it unlikely. The trouble is that since smallpox inoculation has been discontinued there is no easy way in which the efficiency of various modifications of the Jenner method of vaccination can be readily and positively tested by the civilized practitioner. Rather than trust to speculation he is inclined to follow the positive provings of Jenner's age.
THE IMPORTANCE OF THE PRESERVATION OF BODY TEMPERATURE DURING RESUSCITATION OF THE NEW-BORN CHILD.

With the exception of a faintly beating heart, the infant born asphyxiated has all its organs in a state of rest. Functional activity is almost at zero. An infant born dead will have the temperature of the mother. Lying in a room heated to 70° F. uncovered, it will lose ten degrees of temperature in fifteen minutes. Swung through the air, it will lose from twelve to fifteen degrees in as many minutes, depending somewhat upon its plumpness.

An adult exposed to cold that proves fatal is dead before any such loss of temperature prevails. Infant asphyxiation may be due to maternally administered anesthetics, or narcotics, to pressure on the head by forceps or molding, to tonic spasm of the uterus, to intracranial blood-pressure, to pressure on the cord, to shock from manipulations of the cord, to distortion of fetal attitude, and various other causes. In many of these varieties, conspicuously those of anesthesia and narcosis, voluntary resuscitation will ensue if simply the loss of animal heat is prevented for about fifteen minutes.

In a thousand cases of resuscitation the “safety point” will be reached in ten minutes with sixty per cent; in fifteen minutes with twenty-five per cent; in twenty minutes with ten per cent; in twenty-five minutes with three per cent; and the remaining two per cent through a period up to an hour and more.

So long as the fetal heart action continues resuscitation is possible, and this automatic, rhythmic action continues much longer than is generally supposed. Neugebauer reported in the Centralblatt für Gynäkologie of November 26, 1898 (see Obstetrics, January, p. 21), the continued contractions of the heart of a fourteen weeks’ old embryo for three hours, pulsations occurring every two to three minutes. Opitz (see Obstetrics, p. 150) reported in the same journal two cases of fetus at term with the heart beating for thirty minutes, and capable of further contractions after removal under stimulation of a needle. Much longer cases of postpartum heart beating with no respirations have been reported, and no doubt many a still-born child has been laid aside as dead whose heart was still contracting. The ideal method of resuscitation will use the best combination of all aids to respiration, vascular and cardiac circulation, and equilibrium. Blood communication between child and placenta should remain unimpeded; the uterus should not be handled, unless it is bleeding; alternate compression and expansion of the chest should be achieved with freedom; insufflation should be available if required; alternate application of heat and cold,spanking, throat cleansing, etc., etc., should be ready at hand, which may include stretching of the sphincter ani, traction of the tongue, and use of the now ubiquitous electric current; but, above all, should be included the preservation of the body heat up to normal temperature.

The following method of resuscitation has been employed for over a dozen years with growing favor: A vessel one and a half by two feet and six inches deep is half filled with water, as hot as the hand can comfortably bear, and brought close enough to the mother to receive the child without causing traction on the cord. The child is held with the back of the neck resting in one hand and the posterior knee and thigh surfaces in the other. It is then immersed in the hot water, and artificial chest action secured by alternately bringing the knees and head together and apart (Dew’s method), the mouth being kept above water. At intervals of ten to fifteen seconds it is dipped once in very cold water in another bowl, then immediately returned to its hot-water bath. When first placed in the hot water it will turn quite “blue,” due to temporary paralysis and expansion of the skin capillaries. All other adjuvants to resuscitation can be applied with the hot-water immersion kept up practically all the time. In the asphyxia of narcosis, anesthesia, and cerebral congestion, more time is given for the restoration of equilibrium in the circulation by sustaining the body temperature, and in the asphyxia of anemia (pallida) the hot bath wards off the most imminent danger—cold—and sustains the flagging heart. The cord must not be handled. We know that moderate manipulation of it in utero causes heart shock and death. The uterus must not be “Crédée.” If we compress the fundus we might as well sever the cord. The foramen ovale may not close while the blood runs from placenta to child, nor the respirations start up promptly as our anxieties might foolishly desire; but we should not wish to have them do so, for while the mother still breathes for her child its circulation is gaining the equilibrium of its equable surroundings.
Let us condemn and do away for all time with the aerial gyrations of Schultze's method. It is spectacular, but chilling. It is resuscitating to the operator, but deadly for the fetal heart. It is efficient in lung expansion and compression, but no better than Dew's. It gives the stimulation of cold air, but prevents the use of heat, which should be used in the proportion of ten to one in favor of heat. It robs the child in its direst need of its second mother—the placenta—and must succeed promptly or fail altogether. It was conceived with an eye single to lung expansion, and reminds one in its narrowness of wisdom of the bear in the fable which was appointed to keep off the flies from his master who slept. He killed one, which had alighted upon his master's nose, with a large stone, thrown with wonderful accuracy of aim, and wondered why his master did not awake and thank him.—Editorial in Obstetrics for June, 1899.

__A PRESCRIPTION FOR A HEMOSTATIC ANESTHETIC SOLUTION.__

Legrand employs the following solution, particularly in lesions of the mouth, where it is desired to produce anesthesia and arrest small hemorrhages:

- Pure gelatin, 30 grains;
- Chloride of sodium, 8 grains;
- Carbolic acid, 2 grains;
- Hydrochlorate of eucaine B, 8 grains;
- Hydrochlorate of cocaine, 2 grains;
- Distilled water, 3½ ounces.

—Journal des Praticiens, May 13, 1899

__THE TREATMENT OF WHOOPING-COUGH.__

The Journal des Praticiens of May 13, 1899, after pointing out the necessity that the child should live in a room at the proper temperature and have plenty of fresh air, and should be given easily digested food frequently, suggests the following internal treatment for use as soon as it is decided that the child is suffering from the disease:

Externally the chest is rubbed morning and night with a liniment composed of essence of turpentine and oil of sweet almonds, equal parts. Care must be taken that the pure turpentine is employed, and if the child's skin is irritated by it the strength should be decreased. The object is to produce slight reddening but no further irritation of the skin. It is thought that the counter-irritation and the inhalation of the turpentine exercise a favorable influence upon the respiratory passages.

In regard to internal treatment, a good many remedies are employed, but nearly all of them have disadvantages. Aconite is too depressing; belladonna and codeine are too powerful, and check secretions. Antipyrin is apt to interfere with the functions of the kidneys, but inhalations of oxygen are advantageous, and bromoform is recommended by Marfan as distinctly useful. The prescription for bromoform may be as follows:

Chemically pure bromoform, 10 drops; Alcohol (90 per cent), sufficient quantity to hold the bromoform in suspension; Syrup of orange flowers, 1 ounce; Simple syrup, 2 ounces.

This prescription may be given in the dose of one to five teaspoonfuls each twenty-four hours. To a child as young as six years a teaspoonful at seven in the morning, at midday, and at five at night is about the proper dose. It must be remembered that bromoform is a remedy of very great power and that it must be used with some caution.

__THE TREATMENT OF DIABETES.__

Guiranna (La Clinica Medica, An. 5, n. 19) speaks very highly of a diet of fresh vegetables in the treatment of diabetes. In bad cases he finds that much benefit is derived from an exclusive diet of fresh vegetables for a few days, but in ordinary cases a mixed diet is sufficient. The vegetables recommended are endive, cabbage, French beans, artichokes, and in general all green vegetables. Peas and beans, provided they be fresh, may be taken in small quantities (⅜ kilogramme). The author also allows fruits in moderation. The only saccharine substance allowable is levulose, from 50 to 200 grains a day. Probably the reason why green vegetables are tolerated so well is because the starch is converted into levulose and not dextrose. The objection to saccharin and dulcein for sweetening is that they do not represent a food, but a foreign body, in the organism, and being of the aromatic series, and as such non-assimilable, only increase the amount, already copious enough, of waste products in the body. The author has no great faith in drugs, but thinks certain mineral waters, alkalies, massage, and baths more useful.—British Medical Journal, June 24, 1899.
STRUMOUS OPHTHALMIA.

Mr. Maitland Ramsay, in the Edinburgh Medical Journal for July, 1899, gives the following directions as to the treatment of this somewhat obstinate disease:

In addition to the careful supervision of diet, the free elimination of the toxins, which as a result of malassimilation have accumulated in the blood, must in every way be promoted. This is to be accomplished by stimulating the action of the kidneys, the bowels, and the skin—more especially the last. Hence the importance of the hot bath, which the child should have every night at bedtime, diaphoresis being further encouraged by the wearing of a warm flannel nightgown. It is usually advisable first of all to administer a dose of castor oil; but it should be borne in mind that many of these children do not bear purgatives well, as the intestinal mucous membrane is so irritable that troublesome diarrhea is easily induced.

Of drugs, none is so useful as tartar emetic, which should be given in slightly nauseating doses. Its chief virtue depends on its diaphoretic action, and its efficacy is greatly increased when it is administered with a laxative, e.g., powdered rhubarb. If the tongue be brown, a few grains of gray powder may be added with advantage to the rhubarb and antimony combination. Under this treatment it is wonderful how soon the whole appearance of the patient changes. As the power of digestion becomes greater, the skin improves in color, the hands and feet keep warmer; and the child, instead of lying with its face buried in a pillow and fretting and crying when spoken to, is now quite good-tempered, and runs about the ward and amuses itself with its playthings. Any indiscretion in diet will, however, promptly bring on a relapse, for in these cases the conjunctiva reflects the condition of the gastrointestinal mucous membrane even more quickly than the tongue. Intolerance of light, blepharospasm, and increased lacrimation speedily show themselves after some forbidden food has been eaten, while the tongue may not become furred till the second or even the third day. The fear of relapse makes it imperative, therefore, that the treatment be continued for at least a fortnight after the recovery seems complete. Apart from simple digestive agents, such as pepsin, pancreatin, etc., no medicines are as a rule necessary, but most of the patients are benefited by quinine, which, either alone or in combination with an acid, seems to exercise a favorable influence after the acute symptoms have subsided.

Cod-liver oil, compound syrup of the phosphates, syrup of the iodide of iron, etc., are also very valuable remedies, but they should never be prescribed in the early stages, for they then simply add to the difficulties by still further overtaxing the digestive powers. When, however, all feverishness has disappeared, and the tongue is clean, they are decidedly helpful in improving the general nutrition and promoting the repair of any local lesions in the eyes themselves. All syrups, however, such as chemical food, etc., must be used with great caution, lest they disturb digestion, and so determine a relapse. Dusart's syrup of the lacto-phosphate of lime and iron is the most easily assimilated; but as a general rule preparations in which sugar is replaced by glycerin or malt extract are safer. When there is much enlargement of the glands, a mixture of chloride of calcium and iron is very serviceable.

For the first few days of the treatment the patient should be kept in bed, with the eyes shaded from the light; but the use of all poultices and bandages must be strictly prohibited. Whenever improvement begins, the child ought to be encouraged to run about, and, if possible, sent to the country, preferably to a high, dry, bracing locality, and it should live out-of-doors as much as the weather will permit. The seacoast should be avoided, as the glare from the water is apt to prove irritating to the eyes, and to cause a relapse.

The local treatment will necessarily vary according to the stage of the disease. The child's hands and face must be washed frequently, and, as far as possible, it ought to be prevented from crying and rubbing its eyes. The eyes themselves should be bathed night and morning—oftener if there be much discharge—with a warm solution of boracic acid, or a lotion containing perchloride of mercury and belladonna. While the symptoms of acute irritation last, atropine and cocaine, by soothing the nerves of the conjunctiva and diminishing the congestion of its blood-vessels, lessen the photophobia. Whenever the pupil dilates, the child usually opens its eyes; but when the superficial irritation is great, the action of the atropine persists only for a few hours, and in order to obtain full benefit the drug ought to be re-instilled whenever the pupil begins to contract. As the blepharospasm lessens the cocaine may be omitted from the ointment,
and the atropine combined with boracic acid or the red oxide of mercury. Even in cases which have lasted for a long time, leeches or blisters should not be used.

After the acute inflammatory symptoms have somewhat subsided, more stimulating applications are necessary, and calomel and the yellow oxide of mercury are the two favorite remedies at this stage. The former is most serviceable in relieving passive congestions. It must be dried thoroughly andflicked from a camel’s-hair brush into the conjunctival sac. Its beneficial action seems due to the fact that calomel becomes, by the action of the tears, converted into perchloride of mercury. It is therefore necessary to be careful not to use it too freely, or in too coarse powder, for any excess collects in the lower retrotarsal fold, upon which it is apt to have a caustic action. The yellow oxide of mercury often acts like a charm in cases where there is an efflorescence of pustules upon the bulbar conjunctiva. It is best applied in the form of an ointment of the strength of one or two grains of the oxide to a drachm of white vaselin. The bulk of a barley-corn of this is instilled into the conjunctival sac, and the eye gently massaged for a few minutes through the closed eyelids.

In an ordinary case of strumous ophthalmia no further treatment than that just indicated is required. If a case is not making satisfactory progress, careful inquiry should at once be made as to whether the prescribed diet is being strictly attended to, as well as the nightly warm bath.

When the disease has been neglected, complications arise which require special remedies.

1. Swelling of the eyelids, and mucopurulent discharge. The eyes must be kept scrupulously clean by bathing with an antiseptic lotion; and once a day, or oftener, according to the amount of the discharge, the conjunctival surface of the lids should be everted and painted with a two-per-cent solution of nitrate of silver. The presence of a fissure at the external canthus, when such treatment requires it to be carried out, adds greatly to the child’s sufferings; but as this fissure will never heal until the eyes can be opened voluntarily, there is no help for it but to persevere, every care, of course, being taken not to cause unnecessary pain.

2. Inflammation of nasal mucous membrane. This membrane is swollen and ulcerated, and secretes a discharge so acrid that its presence produces much swelling of the alae nasi and the upper lip. If the child be permitted to lie with its face buried in a pillow an eczematous eruption is sure to appear. The nostrils must be kept clean by douching with an alkaline antiseptic lotion, and the nasal mucous membrane brushed afterward with ointment, e.g., a combination of iodol and tannic acid. As in these cases there is always an excess of acidity, alkalis are most serviceable. They should be given in small doses frequently repeated, and there is nothing better than a mixture of calcined magnesia and sulphur, or a combination of sulphate of magnesium with bicarbonate of sodium.

3. Pediculi. In neglected cases this is a very troublesome complication, and one regarding which the nurses must always be warned to be on their guard. In the most filthy cases it is necessary to cut the hair short, and in all the head must be washed with carbolic soap, well dried, and stavesacre ointment rubbed into the roots of the hair. By this means the pediculi themselves are destroyed, but the nits remain firmly attached to the hairs, so that after the first thorough dressing scrupulous cleanliness and the daily use of a small-tooth comb are necessary in order to prevent the vermin from reaccumulating.

4. Ulceration of the cornea. In every case of strumous ophthalmia which has lasted for a long time, the cornea is almost certain to suffer, and whenever ulceration occurs the ulcer becomes the prominent feature, and all treatment is directed toward its cure.

SUPRARENAL GLAND AS A HEMOSTATIC.

A little more than a year ago Schäfer pointed out the hemostatic effect of suprarenal in epistaxis; during the last twelve months the extract has been used abroad to control the hemorrhage in operations in the nose and pharynx. Grünbaum (Journal of Physiology, May 11, 1899) suggests that cases of hematemesis might be benefited by the administration of suprarenal extract, if the active principle were not absorbed sufficiently rapidly to cause a rise in blood-pressure, in which case the hemorrhage would not be controlled. The author made some observations on his own blood-pressure before and after doses of pulverized suprarenal tabloids, the hemostatic properties of which had been tested. An Oliver sphgmodynamometer was used, which, although not correct absolutely, worked excellently as a comparative instrument. The doses taken
were 10, 20, and 30 grains; the blood-pressure was taken every ten minutes for three hours after the dose; no cardiac stimulant vitiated the results of the experiments. In no case was there an appreciable increase in blood-pressure—that is, an increase beyond that of experimental error, which is 4 mm. Hg.

Another series of experiments was carried out on a woman who at one time had given the impression of being afflicted with Addison's disease. Her blood-pressure was normally 118 mm. Hg. when taking imitation suprarenal tabloids; on her being given thirty real tabloids representing 150 grains of the fresh suprarenal gland daily, no rise in blood-pressure occurred, although the treatment was continued for over a week. In one case a rise in blood-pressure was found after the administration of suprarenal; it was in the case of a pregnant woman who had some pigmentation, vomiting, muscular weakness, as shown by the ergograph, and a very low blood-pressure. A rise from 75 mm. Hg. to 91 mm. Hg. was brought about by the administration of suprarenal tabloids, which was not maintained on the omission of the doses. The negative results as regards the alteration of blood-pressure in normal individuals make it probable that suprarenal extract is an ideal hemostatic in cases of hemorrhage from the walls of the alimentary canal or bladder.—*British Medical Journal*, July 1, 1899.

**PROTECTIVE INOCULATION AGAINST PLAGUE AND CHOLERA.**

The speech in which Mr. Haffkine introduced the discussion on preventive inoculation at the Royal Society places us in possession of the main facts and theories which have influenced him in the prosecution of his important work. The problems which he set himself to solve were most intricate and complex, and required talent and perseverance of an exceptional order to bring them to a successful issue. No one who listened to the address which Mr. Haffkine gave in February, 1893, when he came over from the Pasteur Institute in Paris to arrange for his visit to India to test on man the remarkable results he had worked out on animals in the laboratory with reference to the cholera bacillus, could fail to be struck by his enthusiasm, though perhaps some were skeptical of the results which would accrue from his mission to the East. Ferran's failure in Spain was too fresh in their minds to be forgotten, and though Mr. Haffkine explained the reason of failure, and showed that his method differed from Ferran's in securing a pure, stable, and controllable virus, yet the attitude of mind adopted was rather one of hope that he was right than of expectancy. The six years that have passed since then have been for him six years of continuous hard work and devotion to his self-appointed task. Gradually in that time a complete change has taken place in the general attitude toward preventive inoculation, and that change has been effected by the results which Mr. Haffkine has been able to show as following on his extensive experiments in India, not only in cholera but also in plague.

Prophylactic inoculations are based upon the fact that an attack of infectious disease generally leaves the recovered patient more resistant to the second attack. On this foundation rested the work of Jenner and Pasteur, as well as the more recent work of Haffkine, their disciple. It is the success of Jenner and Pasteur which gave rise to the modern conception that artificial immunity may be created against infectious diseases by the introduction into the system of specially prepared and harmless virus; but, as Mr. Haffkine points out, the conception is too general in its nature, and its application, when undefined, is apt to lead to disappointment. The composite character and modifications of a virus, according to the way in which it is prepared, have to be taken into account. For a long time it seemed impossible to produce artificial immunity by derivatives from diphtheria or tetanus virus or from microbes in general, which cause localized infections, and do not, as a rule at least, invade the system. Similarly the different results which the same modification of a virus produces in different species of animals have to be borne in mind. While it now seems safe to assume that a form of prophylactic treatment may be found that will be useful against a particular infectious disease in a particular species of animal, yet that method may not be applicable to another animal or to another disease affecting the same animal. Professor Haffkine believes that it is inattention to variations in circumstances and conditions which has more than anything else checked the success of a number of experimenters.

The study of the anticholera inoculations in India, in which the microbes alone were used as the vaccine, brought up another problem. The Calcutta results showed that
for a period of nearly fourteen months the number of deaths among the inoculated was 22.62 times smaller than amongst the uninoculated, and for the rest of the time under observation the proportion in their favor fell to one and 1.54; but while the absolute number of deaths appeared strikingly influenced by inoculations, the special feature observed was that the proportion of deaths to those attacked among the inoculated was not changed. The fact that case incidence was remarkably affected, while the case mortality was not reduced, presented a new aspect in the problem of preventive medicine, and accordingly, in 1896, when confronted with the problem of working out a prophylactic treatment against plague, Mr. Haffkine determined to obtain not only a lowering of the susceptibility to the disease which he had succeeded in obtaining in cholera, but also a reduction of the case mortality. For that purpose he determined to employ in combination with the plague microbes their extracellular toxins. In order to accumulate these products the bacilli were grown in broth in the ingenious manner described by Mr. Haffkine in his paper. The process is continued for five or six weeks. The microbes are then killed by heating to a temperature ranging from 65° to 70° C., after which the virus is ready for use.

Mr. Haffkine quoted the statistics of three instances. At Byculla jail there were twelve cases and six deaths among 172 uninoculated inmates, and only two cases with no death among 147 inoculated inmates. At Umerkadi jail there were ten cases and six deaths among 127 uninoculated inmates, and three cases with no deaths among 141 inoculated. Again, at Undhera village, there were twenty-seven cases and twenty-six deaths among sixty-four uninoculated inhabitants, and eight cases with three deaths among seventy-one inoculated inhabitants. Other observations, such as those at Lanowle, Kirkee, Damaon, Hubli, Dharwar, and Gadag, presented the same favorable results. The facts at Hubli showed that within a short time a town of nearly 50,000 inhabitants can be inoculated. The difference in the mortality between plague among the inoculated and plague among the non-inoculated was estimated to average over eighty per cent, sometimes reaching as high as ninety per cent. The dose of the prophylactic varied from 3 to 2½ cubic centimeters for an adult, and the duration of the effect was at least a few months, the usual length of an epidemic.

Some of the problems which remain to be worked to perfect the system were mentioned by Mr. Haffkine, and others were referred to by those who joined in the discussion. Though minor points, they are important to complete success of the general application of the system, and we have no doubt that when Mr. Haffkine returns to India after a well-earned rest from labors which have been Herculean, he will be granted full opportunities and the necessary trained assistance in his laboratory to enable him to solve them. The main and most important feature, however, of his six years' work is the grand fact, which Mr. Haffkine has established, that both cholera and plague inoculations are a success, whether they are applied on a small or a large scale, and that in this method we possess a powerful prophylactic against these two most fatal diseases.—British Medical Journal, July 1, 1899.

HIGH ALTITUDE AND HEART DISEASE.

Babcock, of Chicago, concludes an article in the Medical News of July 15, 1899, on this subject with these words:

1. All forms of cardiac disease do not contraindicate sojourn at a high altitude.
2. The ill effects of low atmospheric pressure in some forms of cardiac disease are explicable on the hypothesis of acceleration of venous flow and corresponding quickening of the heart-beats.
3. Consequently those forms with which high altitude is likely to prove incompatible are pronounced aortic or mitral stenosis, and regurgitant disease complicated by pleural and pericardial adhesions.
4. On the other hand, patients with uncomplicated regurgitant lesions, or arteriosclerosis with or without myocardial changes, may endure low atmospheric pressure without injury.

THE QUESTION OF GRELUS IN THE FEEDING OF INFANTS.

This practical question is discussed by Chapin in the Medical Record of August 5, 1899. He believes that besides attenuating the casein, the addition of gruels to cow's milk increases the nutritive value of the food. This is of great service in that class of cases in which bottle-fed babies show stationary or losing weight. The food for such infants may be properly prepared as far as percentages are concerned, and yet they do not thrive. This is especially seen in institution
babies. A proper addition of gruels to milk will not infrequently check wastage. The large proportion of lactose, a carbohydrate, in woman's milk shows the desirability of this food principle to the growing baby. The rapid production and easy dissipation of animal heat in the very young, with active tissue metabolism; indicate the call for some of the carbohydrate series.

Various observers have called attention to the favorable effect of carbohydrates in tending to prevent the putrefaction of proteids in the bowel. Such action is doubtless due to the formation of acids in the intestine, especially in the lower segments. The presence of free acids in the bowel prevents the growth of those intestinal bacteria that thrive in an alkaline medium.

While proper theorizing is desirable in the practice of medicine, the ultimate and final decision upon any therapeutic question must rest upon clinical experience. The writer has tried all kinds of infant feeding with that hardest class of cases, bottle-fed babies in hospital and dispensary practice. By adding gruels to the milk, the best results are obtained with these babies. The theory is that the cereal will help attenuate the curd of cow's milk and aid in the nourishment of the baby; in practice, the infant is not so apt to vomit thick curds, and the tendency to a stationary or losing weight is often lessened. Jacobi, with his long clinical experience, while recognizing and utilizing all the advances in infant feeding, maintains that the use of decoctions of the cereals is of the greatest value as an addition to cow's milk. He finds that even very young infants thrive better when cow's milk is diluted with gruels than when a mere sugar solution is added. In Germany, Heubner, of Berlin, comes to the same conclusions from a wide clinical experience.

The common objection advanced against this method of feeding is that a nursling should not be given starchy food in any form, as its digestive powers cannot cope with this food principle.

While large quantities of starch should be withheld in infancy, even the youngest baby can tolerate and digest a small and proper amount. According to Hammarsten, ptyalin, or salivary diastase, the amylolytic ferment of the saliva, occurs in new-born infants. He also states that pancreatic diastase, which, according to Korowin and Zweifel, is not found in new-born infants and does not appear until more than one month after birth, seems, although not identical with ptyalin, to be nearly related to it. Hence a certain amount of starch can be digested by the newly-born and very young infant.

AN EXPERIMENTAL INVESTIGATION OF THE ACTION OF RED BONE-MARROW ON THE BLOOD IN ANEMIA.

As the result of an investigation made by Fowler, and printed in the Scottish Medical Journal for September, 1899, he reaches the following conclusions:

1. Subcutaneous injections of bone-marrow have no action on the red corpuscles or hemoglobin of a healthy animal. (2) When the red corpuscles and hemoglobin fall below their normal limits, injections of marrow produce a decided rise in both. This rise is well marked, sudden, and of short duration. (3) Along with the increase in the red corpuscles, there is no corresponding improvement in the form of the cells. (4) The active principle is present in an aqueous, but not in an alcoholic, extract of marrow; it is not precipitated by boiling, does not contain iron, and may possibly be a deuteroprotoese.

RELATIVE TOXICITY OF COCAINE AND EUCAINE.

Peck places his conclusions as to this matter in the following words in an article in the Journal of the American Medical Association of September 9, 1899:

1. The action of cocaine is inconstant; one never knows whether the symptoms occasioned by like quantities of the drug, in animals or individuals, under like circumstances, will be similar or dissimilar.

2. The action of eucaine is constant. The symptoms occasioned by the use of like quantities in animals, under like circumstances, and so far as Dr. Peck's experiments have gone, in different individuals also, are the same.

3. The first action of cocaine on the heart is that of a depressant, and on the respiration it is that of a mild stimulant, the after-effects being, on the heart, that of a decided stimulant, and on the respiration that of a decided depressant.

4. The first action of eucaine on both the heart and respiration is that of a stimulant, the after-effects being those of a decided depressant.

5. Cocaine causes death in animals by paralyzing the muscles of the respiratory apparatus, the heart's action continuing in a feeble way for a brief period after breathing ceases.
6. Eucaine causes death in animals by paralyzing the muscles of the heart and of the respiratory apparatus, they ceasing to operate simultaneously.

7. Eucaine in toxic doses nearly always causes nausea and occasionally vomiting.

8. Cocaine is much less nauseating and scarcely ever causes vomiting.

9. Eucaine is decidedly a diuretic, causing renal discharge in a majority of instances in which a toxic dose is used.

10. Cocaine is not a diuretic to any appreciable extent, renal discharge having occurred in only one instance in connection with all Dr. Peck’s experiments.

11. The pupil of the eye, in nearly all cases of cocaine poisoning, does not respond to light and is more or less bulging from its socket.

12. The pupil of the eye in most cases of eucaine poisoning does respond feebly to light, and rarely bulges from its socket.

13. The action of toxic doses of eucaine is more like that of a paralyzing, tetanoiding, convulsion-producing agent, than it is like an anesthetizing one, the plantar and cremasteric reflexes nearly always responding.

14. Toxic doses of cocaine cause general anesthesia in connection with the other symptoms in the majority of cases.

15. True tetanus of all striped muscles of the limbs, and Cheyne-Stokes breathing, nearly always occur with the use of cocaine, but seldom does either occur when eucaine is used.

16. Cocaine is at least three times more toxic than beta eucaine, and alpha eucaine is as toxic as cocaine.

17. Boiling does not destroy the efficacy of cocaine, but it does modify it; and boiling in no degree lessens the efficacy of eucaine.

---

THE TREATMENT OF TUBERCULOSIS.

Lawrence Flick states his belief in the Medical News of September 2, 1899, that a great deal can be accomplished by drugs in the treatment of tuberculosis if the drugs are judiciously used. We have no specifics for tuberculosis and may never get any, but we have valuable adjuvants and are constantly adding new ones to the list. In Dr. Flick’s experience he says he has found iodine the most valuable remedy at our command. He used it in the form of euphenin, which he introduced by inunction. The following is the formula which he employs: Euphenin, 1 dram; oil of rose, 1 minim; oil of anise, 1 drachm; olive oil, 3/4 ounces. Of this he has the patient rub from a teaspoonful to a tablespoonful into the armpits and into the inside of the thighs once or twice a day. Formerly he used iodiform in this way, but owing to its offensive odor he has discarded it in favor of euphenin, which is even richer in iodine than iodiform. As the patient becomes more tolerant of iodine he sometimes reinforces the inunctions by giving the euphenin by the mouth in addition. He has tested the value of this treatment for a long period to convince him that it is real and worthy of confidence. The treatment ought to be kept up for a long time, and even after all symptoms of the disease have disappeared.

The next most valuable drug in Dr. Flick’s experience is creosote. This is of especial value in the more advanced stages of the disease. In all cases of tuberculosis which have advanced to the stage of breaking down he gives creosote in addition to euphenin inunctions as a routine treatment. In order to get the full benefit of creosote large doses should be given. He begins with one drop and increases the dose gradually until the patient takes from forty to fifty drops three times a day. The best vehicle which he has found for administering the drug is hot water. As he increases the dose of creosote he increases the amount of hot water, and in this way his patients find themselves able to take large doses of the drug without inconvenience. The maximum dose is usually taken in a pint of water. As a rule he orders the creosote taken before meals, and is under the impression that it stimulates the appetite. He uses pure beechwood creosote in preference to other preparations because it is less expensive.

The third place in the order of importance in the value of drugs for the treatment of tuberculosis he hesitatingly assigns to strychnine. In what way it acts he does not know, but if given in proper doses it helps to increase weight and improves the heart action. As a rule it ought to be given in large doses, but all patients do not bear large doses well. The dose should be changed from time to time. Other drugs that are useful in properly selected cases are arsenic, digitalis, mercury, both in the form of calomel and corrosive sublimate, belladonna, muriate of ammonia, aromatic spirits of ammonia, nitroglycerin, the mineral acids, and the vegetable tonics. Most of these drugs may be used to advantage for build-
ing up nutrition. Nitroglycerin is useful for checking hemorrhage, ammonia for stimulating the secretions of the bronchial glands.

ERYSIPelas AND ALLIED DISEASES.

The *Edinburgh Medical Journal* for August, 1899, contains an article by Maclachlan in which he suggests the following line of treatment. He thinks that in uncomplicated cases of cutaneous erysipelas no special treatment is required beyond supporting the patient, favoring elimination, and using antiseptics locally to the affected parts. As a further precaution, the air of the sick-room or ward might be charged with vapor containing eucalyptus oil, which proved effective in checking the spread of the disease in an asylum alluded to by Dr. Maclachlan. These preventive measures can scarcely be dispensed with, considering the risks tiny scratches on the body expose one to; and further, we cannot estimate beforehand the inherited tendencies that exist in some individuals to this disease.

Many drugs have been counted as specifics, particularly large doses of tincture of chloride of iron, but Dr. Maclachlan has not been able in his own experience to support Bell and others who have taught this doctrine. He has given in several cases as much as thirty minims every hour, in the hope of arresting the disease, but has been unable to satisfy himself that the medicine exerted any peculiarly curative influence. Whatever tends to contract the capillaries of an inflamed area is likely to do good in diminishing the exudation, and so the tension and pain of the part. Iron is likely to do all this; but there its influence stops. Moreover, it would not be difficult to bring a body of evidence in favor of any drug in a disease that spontaneously subsides.

Not a few drugs, while not markedly affecting the pathogenic cause of a disease, do good by influencing the morbid products of the disease, either by causing or promoting their absorption or checking their accumulation, and, so to speak, relieving the mechanical disabilities of the affected part. Under this head the author places aconite (praised by Ringer), purgatives, diaphoretics, etc., all of which may be more or less useful, when properly used, although in no sense curative.

With regard to surgical cellulitis and its congeners, Dr. Maclachlan says he supposes little doubt exists as to there being no specific drug. In such circumstances the best treatment is to conserve the vital processes, an expression used by Gull in regard to any treatment. This object is achieved sometimes by what seems to be diametrically opposed lines of treatment. There is the patient and his disease. What seems best for the patient may not be best for that part of him which is the seat of morbid action, and *vice versa*. When in doubt, one must treat the patient, and take the cue from the general state of the body and not from the local affected part.

The surgical forms of the disease, including puerperal peritonitis, and, for that part of it, even septic pleurisy, he has been in the habit of treating in the following way:

*Dietetic.*—He relies chiefly on brandy, eggs, and milk, with good beef tea by way of a change. The brandy he uses as a food and a dietetic stimulant, giving one or two teaspoonfuls hourly in bad cases, with about a wineglassful of milk, or egg and milk whipped, with some sugar added, or a corresponding amount of beef tea.

It is of great importance to regulate the quantity of food given to a patient according to the powers of the stomach. A patient may take a wineglassful of liquid food hourly, whose stomach could not tolerate a cupful every two hours. Sometimes it may be necessary to give only a tablespoonful or even a teaspoonful at a time, frequently repeated. If the stomach is very irritable, and vomiting sets in, he withholds food by the mouth for several hours, giving the patient a teaspoonful occasionally of weak brandy and water (a teaspoonful to the wineglassful), and applies mustard poultices to the epigastic region. This generally succeeds. When vomiting stops food may be cautiously given.

In regard to the question of stimulants in acute disease, Dr. Maclachlan says he has never been able to disabuse his mind of the idea that it is possible to poison a sick person, as well as a healthy individual, by the indiscriminate use of alcohol. It is true that some diseases—e.g., diphtheria—would seem to make a sick person more tolerant of alcohol. Nevertheless, he prefers to give ammonia when a pure stimulant is required. He looks upon repeated narcotic doses of alcohol as dangerous in critical illnesses, as tending to paralyze the higher centers, and to unhinge the nervous mechanism generally.

Sir William Gairdner has, for the last thirty or forty years, championed the cause of great moderation in the use of stimulants in acute disease. His teaching and his experience...
may be said to have given the death-blow to that of Todd, which consisted in pouring in alcoholic stimulants in proportion to the weakness of the patient. Indeed, Gairdner's teaching practically amounts to this, namely, that alcohol should be used in acute disease on the same lines as in comparative health, "to quicken and develop the appetite for real food and the power of assimilating it," and that stimulants should not be given except with food, unless for the purpose (as a drug) of procuring sleep. Gairdner regards alcohol—even if hypothetically a food—a bad food in acute disease. And his successful record of the treatment of cases of typhus fever was achieved without employing alcohol at all, in the vast majority of his cases. Dr. Maclachlan agrees entirely with Sir William Gairdner's teaching, except that he regards alcohol as a food in acute disease, as well as a dietetic stimulant; only it is a food that must be given in small quantities and in a diluted state, to avoid its exhausting stimulating effects, and imperfect assimilation.

A very sick patient is practically a starving one, and very large doses of alcohol cannot be a fictitious danger. During the night the patient should be fed twice or thrice at least. Little and often is Dr. Maclachlan's motto, both in regard to food and drink, in severe illnesses.

Medical.—In the diseases under consideration, there are three drugs he pins his faith to, namely, opium, digitalis, and quinine, given in his opinion in the order of therapeutic merit. He prefers to give them in pill form. The dose of the several ingredients may be altered to suit the exigencies of the case. He generally gives one grain of opium, one grain of quinine, and one-fourth grain of digitalis, every two, three, or four hours, according to circumstances. The combination of these three drugs in pill form generally goes by the name of Niemeyer's pill. It is most valuable in supporting the circulation at the dangerous period of an illness, preventing death from heart failure—the common cause of death in acute disease. Dr. Maclachlan attributes the successful issue of most of the cases narrated above as chiefly due to this pill.

**IMPROPTU POST-MORTEM CÆSARIAN SECTION.**

Attention has recently been called by Colle (Echo Médical du Nord, June 25, 1899) to the grave legal responsibility assumed by a physician who undertakes to save an unborn infant's life by performing Cæsarian section upon a recently dead mother without, as would usually be the case, the permission of the husband or relatives of the deceased. It seems that Colle was calling upon a patient whose confinement was expected shortly, when she suddenly fell dead in his presence. Hastily securing instruments from his house, he delivered within fifteen minutes a living child by abdominal section. Naturally rumors began to circulate that the mother was not dead, and the possible legal risk the doctor had assumed so impressed itself upon him that he later advocated the delivery of the child in similar cases by accouchement forcé.

So far as we know, there has been no malpractice suit brought in any similar case, which is rather strange; but the suggestion of Colle is well taken.

Some years ago the writer had a case of sudden death of the mother in which he delivered the child by accouchement forcé, when the thought of what might have been had he done a Cæsarian section was very deeply impressed upon him. The patient, an Irish primipara in the first stage of labor, died suddenly while attended by an assistant. On arrival, twenty minutes after death, the writer found the main room of the tenement house occupied by some sixty highly excited friends of the deceased, and the young doctor suffering from cold sweats faithfully standing by the patient in the adjoining room.

Finding the mother's heart silent, and quickly realizing the impossibility of securing the consent of any of the assembled congregation in time to render Cæsarian section feasible, and that it would be worth one's life to so operate without consent, we promptly shut the door, took a pocket penknife, and slit the cervix thoroughly and delivered a still-born child. The time required to effect delivery was not more than two to three minutes. There was no external wound, and so there was no suggestion of fault-finding to the crowd of emotional friends, many of whom would have been only too glad to vent their feelings against a doctor rather than blind fate. Delivery through the vagina instead of the abdominal wall can be accomplished with the forceps or by version in almost as short a time as by abdominal section, except where the pelvis might be contracted.
The chief consideration in this subject is not, however, the safest way to do the operation—safest for the physician—but whether it should ever be done until the death of the mother is a certainty.

Dohrn has made a special study of this question (Volkmann's Samml., No. 188), and cites several cases in which maternal death was apparent and Cesarian section performed. The first was that of a living child, extracted seven hours after supposed death (it being held that the mother must have been alive); a second referred to resuscitation of a woman after apparent death from hemorrhage; while a third, the most significant of all, was an apparent death from meningitis, where after three-quarters of an hour of vain effort to resuscitate the woman, the attendant was about to perform the Cesarian operation when the patient came to life.

Statistics kept for many years in Württemberg show that out of 100,000 confinements, the Cesarian section had been performed, post-mortem, on thirty-six women.

Kendall (Virginia Medical Semi-Monthly, Jan. 27, 1898) reported two cases of post-mortem Cesarian section following rupture of the uterus, with one child living.

Considering the comparatively small number of children saved out of the number delivered by post-mortem Cesarian section, and the frightful character of the situation for both mother and physician, where the operation might be mistakenly performed upon a living woman, it is certainly best for the physician to delay operation while any doubt remains of the mother's demise. Further, it would seem best to select the vaginal route for delivery whenever possible.—Obstetrics, August, 1899.

THE TREATMENT OF ECLAMPSIA.

In Obstetrics for August, 1899, Dr. Lee gives the following directions for the treatment of this formidable condition:

1. Protect the patient from the vehemence of the convulsion. Absolute quiet in bed, surrounded with pillows; remove false teeth; have a gag near at hand to put between the teeth to avoid injury to the tongue. A clothes-pin covered with a soft cloth and placed between the jaws so as to develop the elasticity of its arms answers very well. The room should be darkened, all noises rigorously excluded, no jarring of the bed, slamming of doors, talking, moving about, etc., and the patient should be disturbed not more than is absolutely essential. These are not minor points, but are important, as convulsions are caused by the slightest external impression or irritation.

2. Narcotize the woman. The arguments as to utility and safety of this procedure are not yet closed, but they seem to be tending toward the recognition of its value in the majority of cases. Give one-quarter of a grain of morphine hypodermically every thirty minutes until three-fourths of a grain is taken. Give forty-five grains of chloral per rectum, and repeat in two hours, if necessary. Chloroform is now recommended only when one convulsion follows the other in rapid succession. Under the above treatment this will not occur, so the writer desires the use of chloroform restricted to anesthesia for operative purposes.

3. Shall bleeding be practiced? The pendulum is swinging back. In cases where the convulsions occur in spite of the above medication, where the pulse is strong and full, face flushed or even cyanotic, where, in short, the case may be called sthenic or apoplectic, bleeding will do good. It is not necessary in all cases, but when it is, it should be practiced until there is a perceptible effect on the pulse. In cases where the pulse is weak and running, or absent, where cyanosis and pallor are combined, where the case is of the asthenic variety, the utility of bleeding is doubtful. Stimulation is indicated—strychnine, nitroglycerin, camphorated oil. Where the right heart is engorged, and pulmonary edema threatens, bleeding, together with powerful cardiac stimulation, may tide the patient over. The pulse here is not the guide. In general it may be said regarding venesection in eclampsia that it has a place in the treatment, and an important place, but that careful discrimination should be used as to the cases in which it is practiced, the amount of blood withdrawn, the period at which it is drawn, and in making deductions regarding effect.

4. Aid elimination. The means given previously may be employed, adapting them to the conditions present. If the labor is in active progress, little can be done with hot packs, nor is it desirable to have the field of operation flooded with fluid feces, the result of croton oil. Diuretics are too slow during active eclampsia. An excellent remedy, applicable to all stages of labor, is the subcutaneous injection of normal saline solution. The effect on the kidneys is remarkable. It has been used in combination with venesc-
tion to supply the place of the blood withdrawn, and is sometimes called "washing the blood," theoretically a good procedure. When labor is not in progress, and during the puerperium, all the efficient eliminatory measures may and should be employed.

Treatment During Pregnancy.—In a given case of eclampsia, when labor has not yet begun, try to tide the patient over the present danger by the means just given, and induce labor after the tendency to convulsions is past, or wait till labor comes on naturally. In the modern trend toward operative measures, those successful cases, not a few, where expectancy and medication lead to a favorable termination are being ignored.

Theoretically, if one should induce labor when eclampsia is threatening, one should end the pregnancy when it has broken out. Clinically, however, one can often overcome the convulsions, the fetus may die and be expelled, and, what is not so rare that it may be neglected, the patient may go on to term, and have a living child. If the convulsions are at all severe, labor usually comes on without much delay.

The dangers of injury and shock in the rapid dilatation and emptying of the uterus, and the many irritations to the already overwrought nervous system made by it, may more than outweigh the advantages of the immediate termination of pregnancy. Should medicinal treatment have no effect, the convulsions getting more frequent, longer, harder, or the pulse getting more frequent with a rising temperature, induce labor. Puncture the bag of waters first. In a third of the cases the convulsions cease, in another third they become less strong, but in the rest they do not improve. Labor usually comes on at once, especially if the fits are violent. They stimulate the uterus, and labor pains are often strong. If necessary to hasten the labor, dilate the cervix with Barnes's bag or the colpeurynter.

Treatment During Labor.—All authors are agreed that during labor one should terminate the process as soon as possible. The greatest differences exist, however, in regard to the amount of force to be employed. Accouchement forcé should almost never be used. By this is meant the rapid dilatation of the cervix, incising it if necessary, and the immediate extraction of the child.

Dr. De Lee says he cannot agree with those who say that it is possible safely to stretch, tear, and cut the cervix open and extract the fetus in thirty minutes to an hour. Unless the upper part of the cervix is effaced—that is, drawn up into the body of the uterus (carrying the circular artery with it)—the dangers of rapid dilatation by any of the means employed are great. Laceration of the cervix, even to the peritoneal cavity, hemorrhage even fatal, later sepsis, have occurred often enough to warn against this procedure. When the cervix is effaced, and the os begins to dilate, the case has an entirely different aspect; then the dilatation by the hand or incision is comparatively without danger. It must never be forgotten that stretching cannot replace the natural process of effacement and dilatation, and that it is therefore in the highest degree desirable, in cases where operative delivery is to be made, to wait until the cervix is thinned out—that is, shortened—and the dilatation at least beginning before it is attempted. The circular artery is then out of reach, and the incisions, as given by Dührssen, or the lacerations, are not so dangerous.

The only means to produce this effacement of the cervix is the uterine action. Stretching from below or pulling rubber bags through will not do it, except insomuch as they produce uterine contractions. In cases, therefore, where rapid delivery is indicated, the writer uses Barnes's bags and the colpeurynter to dilate the cervix, as they at the same time evoke pains and hasten the shortening of the cervix. Manual dilatation of the cervix is accomplished by a method similar to that described by Edgar, of New York, which the writer has used for five years with success, varied by a few failures. The cervix will sometimes tear under the manipulations so that recourse must be had to incisions, or it will not give way to any justifiable force, when the scissors may again be necessary.

The delivery is best accomplished by the forceps. Version is undesirable in eclampsia. If the child is dead, by all means perform craniotomy.

If there are perineal or vaginal tears, repair them; if cervical, leave them alone, unless hemorrhage gives the indication. The delivery of the placenta is as usual. If contraction and retraction of the uterus are good, postpartum hemorrhage is not to be feared. Do not tampon the uterus if at all avoidable.

The child is not seldom asphyxiated; it may be narcotized by the drugs given the mother, and it may have convulsions similar to those of the mother.

It is well to remember that in eclampsia
labor is usually rapid, and the patient being unconscious, the baby may be born unexpectedly under the bedclothes. It is well to leave the case to nature if the labor is progressing rapidly, if the convulsions are not too severe, if the color of the patient is not cyanotic, if the pulse is good, the fever not above 102°, and there be no signs of edema pulmonum.

As soon, however, as the cervix is completely dilated there is usually no need to wait longer, and the delivery may be completed under chloroform. Only in the gravest emergency should forcible means to empty the uterus be employed. Cæsarian section has no place in the treatment of eclampsia unless the woman is about to die and the child is alive.

From the above it may be seen that Dr. De Lee leans toward an expectant plan of treatment of eclampsia; but it will be seen also that under proper indications on the part of the mother, active, decisive, operative measures are advised.

_Treatment During the Puerperium._—Those measures given above—that is, those appropriate to all cases—come into play here to the fullest extent. The eliminators must be stimulated to the full safe limit. Narcotics must be used more sparingly now, unless the convulsions are very violent, as it seems that they increase and prolong the coma, and lock up the secretions. During the labor where the irritation from the genitals is being kept up, narcotics are necessary, and we must take their bad effects with the good. No drug is an unalloyed good.

Saline solution may be given in large doses hypodermically, and oxygen, which is supposed to aid elimination by the lungs. Dr. De Lee has used oxygen in only one case—puerperal eclampsia—but there was no effect, not even on the cyanosis.

_Veratrum viride_ has been much extolled as a specific for eclampsia, and it did for a time take that part of the place of bleeding that chloroform did not usurp. Now bleeding is taking its place again to the disuse of chloroform, and veratrum is being less used than it was. It is said that by this drug the pulse may be kept at 60, and then no convulsions can occur. Dr. De Lee says he has had but little recourse to this drug, but in one case the fits recurred even while it was being pushed to its physiological effect. It may be used with other remedies.

In general the treatment of this grave accident is much the same as the treatment of any other disease—not one drug or course of procedure for all cases, but a proper individualization of the cases and a careful application of the method suited to each.

**QUININE IN MALARIAL HEMOGLOBINURIA.**

The _Memphis Lancet_ for September, 1899, a journal published in a part of the country in which malarial hematuria is common, replies editorially to an advocate of the use of quinine as follows:

"The _Journal of the American Medical Association_ bemoans the fact that it still reads the 'assertion' that the administration of quinine in malarial hemoglobinuria aggravates the 'symptom,' and then asserts that very few practitioners in the malarial districts believe that quinine will produce this condition.

"The _Journal_, by rules of logic which are naive, to say the least, says: 'Why the hemoglobinuria of malarial origin has been singled out among all the other varieties and stated to be increased by the use of quinine is not clear. Thus we have (1) paroxysmal hemoglobinuria, and (2) toxic hemoglobinuria, including that due to chlorate of potash, carbolic acid, naphthal, carbon dioxide, and the poisons of infectious fevers, etc.' It says further: 'The bright-red urine observed is not always a hematuria—in fact, a hematuria is the rare exception, for hemorrhages, of whatever nature, are uncommon in all varieties of malaria.'

"It is very easy to sit on the editorial tri-pod on the shore of Lake Michigan and, in the above _ipse dixit_ style, dictate to experienced men how they should treat a 'symptom,' of which the editor shows his ignorance by calling it such. Malarial hematuria (one term is as good as another, since both are incorrect) is a pathologic entity, with a symptom-complex all its own. To place it in a category with other conditions which also have one of the symptoms does not strike the ignorant swamp doctor as good logic. Now, to begin with, the form of malarial fever accompanied by bright-red urine we denominate hemorrhagic malarial fever. There is a distinct hemorrhage, and it is most effectually treated with quinine, and rationally so, because the malaria is in an active form and requires the classic remedy for its removal. Not so in the other condition; here the bulk of the color is due to methemoglobin, the urine is black or the color of port wine, and, the _Journal_ to the
contrary notwithstanding, there is always some blood present. In this condition the malarial organism is either already absent or is rapidly disappearing from the blood.

"The symptoms of icteric hemoglobinuria of malarial origin are about as follows: After a variable history of previous intermit-tents, treated with quinine, the patient is suddenly taken with a chill, lasting from a few minutes to an hour, the thermometer indicating from 101° to 106°, usually about 103°. This is followed by no increase of temperature and absolutely no sweating. After a short time, from a few minutes to an hour, the patient will pass with great vesical tenesmus from 30 to 300 cubic centimeters of dark-colored urine; if the quantity is small it is inky black, and the prognosis is bad. The urine is highly albuminous, and contains a variable number of blood disks, mostly bleached out; the specific gravity is from 1,025 to 1,040. If the patient is still under the influence of quinine, a second or third rigor may appear, without any periodicity, and each additional dose, with mathematical precision, will bring on a paroxysm, and each paroxysm is followed by darker urine, but if no more rigors appear it will gradually clear up. The patient has an anxious face, rapid, sighing respiration, a rapid, feeble pulse, and more or less nausea. In from six to ten hours after the onset active vomiting appears, which is projectile, the skin becomes markedly jaundiced (darker than obstructive jaundice), the bowels are obstinately constipated, and the shock becomes more marked. The blood in the beginning may contain from three to four million red cells, some plasmodia, and there may be seen some phagocytosis. In twelve hours the count may be one and a half million, and the plasmodia may have disappeared; even at the autopsy they may be absent in the internal organs.

"In favorable cases, after sharp elimination, all the symptoms gradually disappear; the stools, which were at first black and tarry, become lighter and of a golden-yellow color; the urine is voided frequently, becomes more dilute, and contains epithelia and all kinds of casts. In fatal cases the rigors continue, the patient becomes delirious, suppression sets in, and he dies with 'uremia.' Or there may be amelioration of symptoms, but with suppression, the patient will feel well and will not believe that he is certainly doomed, and may live eight days after complete suppression. In some few rare cases the plasmodia may persist and give rise to a febrile movement; in such we use methylene blue, some preferring sodium thiosulphate.

"Now, the writer will tell the learned editor of the journal a secret: he has never seen a case treated with quinine recover; on the other hand, by the eliminative treatment the majority of cases make a rapid recovery. This is no editorial bombast, but can be attested by thousands of swamp inhabitants. If a malarial infection is promptly and scientifically treated with quinine this peculiar disorder can be positively prevented, but the dilatory and improper use of it in the face of a malarial cachexia will certainly bring on an attack of methemoglobinuria in a susceptible individual.

"The writer has seen several cases of quinine methemoglobinuria; it has no existence apart from malarial cachexia. The editor of the journal can find any number of such cases in the Mississippi valley, providing he has money enough to induce a subject to take a dose of quinine; they generally take arsenic. It seems to be a chronic condition. We admit that we do not understand it, but know, however, that in chronic malaria the hemoglobin percentage falls after quinine is exhibited, just like the pulmonary effect of a mercurial inunction in secondary syphilis."

ACOIN, A NEW LOCAL ANESTHETIC.

R. L. RANDOLPH, of Baltimore, writes as follows of this new drug in the Ophthalmic Record for August, 1899. He begins by reminding us that in the January number of the Therapeutische Monatshefte there is an account of the discovery of a new local anesthetic — acoin — by Trolldenier, of Dresden. Trolldenier's first experiments to show the toxic properties of this product were made on dogs. His results demonstrated that acoin was much less poisonous than cocaine.

The anesthetic properties were tested on the rabbit's eye. At first the powder was tried, and then concentrated solutions; but in these forms it proved too irritating, though it produced anesthesia which lasted "several days." With weak solutions these results were obtained: 1:10,000 produced anesthesia lasting for fifteen minutes; 1:4000 produced anesthesia lasting for thirty minutes; 1:2000 produced anesthesia lasting for sixty minutes; 1:1000 produced anesthesia lasting for 40–80 minutes; 1:40 produced anesthesia lasting for over a day.

Solutions of 1:40 were irritating, though
they produced no injury. It was found that
the solutions were but slightly influenced by
light, and when exposed to the air from three
to eleven days were shown to be sterile.

Dr. Randolph says so far as he knows
acoin has not yet been tested upon the
human eye. His first experiments were
made with a solution of 1:3000. With this
solution he has extracted fifteen foreign
bodies from the cornea. It was noticeable,
however, that in those cases where the
foreign body had been embedded for some
time and where there was congestion, re-
peated instillations were necessary to make
the removal possible, and even then the anes-
thesia did not seem as complete as with
either cocaine or holocaine.

Where there was no congestion the re-
moval of the foreign body was painless.
One pterygium was removed, and the author
noticed no difference in the anesthesia from
that produced by either cocaine or holocaine.
Two tarsal tumors were opened and curetted,
and the operations were about as painful as
when performed under cocaine or under holoc-
aine. He has had no opportunity of making
the corneal incision, but says he should think
that acoin would produce satisfactory anes-
thesia for such an operation so long as the
eye was not in a condition of irritation. The
stinging following the instillation of a drop
of acoin is greater than that after cocaine.
This was shown conclusively. A drop of
acoin was dropped into one eye and a drop
of cocaine into the other, and in every case
the acoin was more painful. In this respect
it resembles holocaine. It took quite as long
to produce satisfactory anesthesia as it does
with cocaine, and longer than it does with
holocaine. In this respect his results do not
agree with those of Trolldenier and Hesse,
who call attention to the rapidity of its ac-
tion. It will be remembered, however, that
the experiments of these observers were made
on rabbits, and from the well known behavior
of these animals on the operating table we
would not be inclined to think that their
sensitive nerves were very highly developed.

Acoin is a white powder, quite soluble in
water in the proportion used in the author's
experiments—i.e., 4/3 grains to the ounce of
water. It is derived from guanin, which is
found in almost all animal and vegetable
cellular tissue. Acoin is related to caffeine
and theobromine.

Randolph concludes that:

1. Acoin in solutions of 1:100 and 1:300
produces satisfactory anesthesia in an uninri-
tated eye in about the same length of time
as cocaine.

2. In more than one case where the eye
was congested repeated instillations of acoin
were inadequate to produce satisfactory anes-
thesia.

3. Inspection of the cornea with a high-
power lens failed to show any defects in the
epithelium after its use.

4. Acoin has no effect upon accommoda-
tion.

5. It has no effect upon the size of the
pupil.

6. It does not increase intra-ocular ten-
sion.

7. Several experiments showed that the
staphylococcus pyogenes albus did not grow
in agar which contained acoin in the propor-
tion used in the clinic, and furthermore, that
exposure of this organism to the action of
acoin for twenty-four hours was followed by
the death of the organism. This would look
as though acoin were not only an inhibitor
of the growth of the staphylococcus albus,
but that it also killed this organism after a
certain length of time.

It is of course evident that conclusions
drawn from this limited experience with
acoin may have to undergo more or less
modification with further trial.

ON THE CONSERVATIVE TREATMENT
OF TUBERCULAR JOINTS AND COLD
ABSCESSES, AS PRACTICED BY
MIKULICZ OF BRESLAU—
1890 TO 1896.

Cathcart (Scottish Medical and Surgical
Journal, March, 1899) states that for some
years past, in addition to fixation and rest,
two very simple means of treating such cases
have been in use—i.e., the injection of iodo-
form, and the artificial production of venous
congestion known as Bier’s treatment.
Alusions have been made to each of these in
the medical papers from time to time, but as
so many other methods have also been advos-
cated we are often at a loss to know which
of them may be expected to take a perma-
nent place among therapeutic measures. In
coming to a decision in such questions we
naturally value the opinion of men of high
standing and wide experience, who have had
ample opportunity of watching such results.
Professor Mikulicz is one of these. He has
advocated the use of iodoform since 1882,
and is so well known as a surgeon that we
may be sure that his preference for non-
operative measures is certainly not due to any want of ability and readiness to operate, if operation would serve the purpose as well.

Mikulicz uses only a ten-per-cent emulsion of iodoform in glycerin. One great advantage of glycerin over other agents is that it is a strong antiseptic. It will destroy all the known pus-forming organisms, and as iodoform outside of the body is practically an inert powder, this saves much trouble and anxiety.

With regard to the dangers of the iodoform-glycerin treatment, we are told that all authors are agreed that a careful attention to the proper dosage makes it quite possible to avoid the danger of poisoning. The symptoms that have been described of an excessive dose of iodoform are severe mental perturbation, raised temperature, rapid pulse, paleness of the face, fixed eyes, spasmodic movement, albumin and strong iodoform reaction in the urine, and the latter also in the saliva. The test consists in adding a little starch paste with sulphuric and nitric acid to the suspected fluid; the iodine is set free and turns the starch blue.

But glycerin itself has been shown capable of producing toxic symptoms. In slight cases there is a rise of temperature within twenty-four hours of the injection to about 38.5° C., with a pulse of about 115; these symptoms generally subside again in twenty-four hours. For a few hours blood pigment is found in the urine, but no kidney elements, nor blood-corpuscles. Corresponding to the blood pigment there are traces of albumin. In more severe cases the temperature often reaches 39° C.; urine is of a deep brown color, and has a considerable sediment containing hyaline and granular tube casts, and a reddish-brown detritus of amorphous lime salts, but no blood-corpuscles. In a fatal case the collapse prevented the temperature from rising, but the pulse went up to 160; there was also sickness, vomiting, great thirst, restlessness, stupor ending in coma. Urine decreased in quantity, and of a dark brown color. Death on the third day. At the post-mortem examination a high degree of acute parenchymatous nephritis was the chief pathological change found. This was a case of hip joint disease with abscesses in a child aged four years. The disease had been treated by Billroth's method, and from 60 to 65 cubic centimeters of iodoform-glycerin had been used.

Outside the body iodoform is practically inert, but when injected into a chronic abscess or other tubercular area it attacks the bacilli apparently after having been decomposed. Its action on the tissues is to increase the development of connective tissue. The clinical value of iodoform in tuberculosis is undoubted, and that for our present purpose is sufficient.

Glycerin is destructive to bacteria, and although dangerous to the patient if injected in too large a quantity, it may be safely used if the proper dosage is respected.

For puncture and injection of abscesses a medium-sized trocar is needed, which fits tightly into the point of a syringe. In case the trocar should become blocked with curdy matter, a sound should be at hand to clear the bore.

For parenchymatous injection and for small abscesses a metal-mounted glass syringe is recommended, holding about fifteen cubic centimeters. It should have rings on the piston and barrel to enable pressure to be made with greater ease. The sharp-pointed cannula should be of different lengths, and should vary from 0.9 to 1.5 millimeters in diameter. They should screw on to the syringe to prevent their starting out when pressure is being exerted. Before use the cannula should be boiled and the syringe soaked in carbolic solution for several hours.

The quantity of the fluid injected depends on circumstances. For parenchymatous injection into the substance of pulpy synovial membrane, from four cubic centimeters in young children to thirty cubic centimeters in adults may be used, but it is better to begin with small doses and watch the results. For cold abscesses larger quantities may be employed, because the absorption from the abscess walls, which are protected by granulations, is much less than from fresh surfaces. As much as 100 cubic centimeters may be used for adults, and proportionately less for children. If the granulation wall of the abscess has been removed by operation, a much less quantity must be used. On the withdrawal of the trocar a pad of gauze is fixed in position with crossing pieces of sticking-plaster, and over all compression is produced by overlapping turns of sticking-plaster. If the pus should be so thick that an incision is necessary, the wound is sewn up at once.

In the case of abscess an oblique puncture is considered advisable, and if the skin over the abscess should be thin and in danger of giving way, the puncture should be carried
through the sound skin at a little distance from the place where pointing has begun. When this is done the thin skin often recovers.

In parenchymatous injection, or when injecting undistended joints, it is more difficult to disseminate the iodoform than where simple abscesses are being dealt with. Tubercular joint cavities, too, are apt to be subdivided into separate compartments, and these have to be dealt with individually. The action of iodoform is confined to the part to which it is applied. Only a slight amount of dissemination occurs through the lymph stream, and that merely within a small radius from the place where it is injected.

Owing to the fact that the dissemination of iodoform is limited, the method of carrying out parenchymatous injection has to be adapted to meet this difficulty. The various parts of the joint have to be attacked in succession. The needle is plunged deeply in, and firm pressure is exerted upon the piston of the syringe till the point of the needle feels loose; it is then withdrawn a little, and the same is done again. Before taking out the needle it is thrust in a new direction, and the same procedure is adopted till the required quantity has been used. Next time another part of the joint is selected, and so on till the whole of the affected tissues has been overtaken. Even softened bones can be dealt with in the same way, but much greater pressure is required.

To provide for the swelling and tenderness that may be expected, when the lower limbs are affected weights are lightened, bandages loosened, and limbs previously free are steadied with sand-bags; until the reaction is over patients who were going about are kept in bed. Except where the pelvis or lower limbs are affected, however, confinement to bed is not thought necessary. Sequestra in bone are not to be taken as necessarily contraindicating a trial of iodoform injection. If the neighboring parts of bone can be infiltrated with the emulsion, the bacilli will be killed, and the sequestrum may be gradually absorbed.

The injections are made at intervals of from eight to fourteen days as a general rule; sometimes much longer, but never under five days. The length of the interval is regulated by the amount of reaction, which should always have completely subsided before the next injection is undertaken. Where simple spaces are being injected in joint cavities or abscesses, the interval is longer, because the drug is generally brought into contact with the whole surface at the first injection.

The fluid distention in an abscess or joint is increased by the injection for the first two or three days. After that it gradually subsides, and in favorable cases disappears in from four to six weeks. The abscess becomes a scar, and instead of the hydrops there is a thickening round the joint with more or less disturbance of its function. The final disappearance of the fluid may be hastened sometimes by the pressure of an elastic bandage. A second puncture may be made at the end of from four to six weeks, but if the fluid found in the cavity then contains iodoform, a further addition of the drug is not necessary. Many abscesses are cured by a single injection; seldom does it need to be repeated more than once. Where an abscess complicates pulpy degeneration the two forms of treatment are combined—i.e., the abscess is injected at long intervals and the synovial thickening receives parenchymatous injection at shorter intervals.

Billroth's method previously alluded to has been employed in certain cases by Mikulicz. Tubercular foci and granulation tissue are scraped away, and bleeding stopped by plugging with iodoform gauze or ligature of vessels when necessary. The wound is then closed by sutures, with the exception of a narrow aperture left for the removal of the gauze and for the subsequent injection of the iodoform and glycerin; it being always remembered that the absorption is much greater from fresh surfaces than it would otherwise be.

Cases coming for treatment with fistulae already in existence are not so easy nor so satisfactory to deal with. Sometimes sinuses may be scraped out and dealt with by Billroth's method. Where the whole sinus cannot be reached, however, this plan should not be employed, and we must trust to injection of the emulsion under pressure. A conical nozzle is pushed into the fistulous opening, and if too small to block it, is supported by a plug of gauze; the fluid is then forced firmly along the sinus and is retained, under pressure by the finger or a plug of gauze, for about ten minutes after the nozzle is withdrawn. After that a plug of gauze is fixed over the opening with sticking-plaster, and compression is maintained with an elastic bandage for several hours. Such injections may be repeated twice or thrice a week, depending upon the amount of reaction.
So far as the pulpy membrane and the tubercular bone are concerned, the only rule is to inject into the part which seems to be diseased; but the cavities of the different joints are best reached from the points which Krause showed after careful investigation to be most suitable.

For the wrist-joint points should be chosen just below the styloid processes of the radius and ulna.

For the elbow, the needle should enter just over the head of the radius in front. At the back the cavity of the joint may be reached from the radial side, the thickened capsule on either side of the olecranon.

For the shoulder Krause thought it better to work laterally from the coracoid process or from the spine of the scapula where it joins the acromion.

The ankle-joint is accessible from the apices of the malleoli. The needle is passed at first directly inward, and its point is afterwards turned up. The thickened capsule may be felt on either side of the tendo Achillis behind, also in front, and is everywhere accessible.

The tarsal bones and joints can be most easily reached from the dorsum and sides of the foot.

The knee can be easily entered by a puncture on either side of, or just above, the patella. The subcrural bursa should not be omitted in tubercular synovitis. The needle to reach it should be passed through the tendon of the quadriceps.

For the hip-joint, either Krause's or Bün-ger's points may be used. The former directs the patient to be laid on his back and the thigh extended, adducted, and slightly rotated inward; a long needle is then entered above the great trochanter at right angles to the axis of the thigh, and is pushed in until it strikes the head of the femur or the neck just below the head; when guided upwards over the head it enters the joint. Bün-ger directs the injection to be made as follows: From the place where the femoral artery crosses the ramus of the pubes a line is drawn to the tip of the trochanter, and the needle is entered at the point where this line crosses the inner border of the sartorius muscle; it is then carried directly back into the joint. Both methods have been used at Breslau to reach the cavity of the joint, and also to attack the swollen synovial membrane. The back of the joint is accessible from the posterior border of the great trochanter.

Psoas abscesses are punctured as soon as they come sufficiently near the surface to allow of their being reached without fear of passing through the peritoneum. Otherwise there would be a risk of causing tubercular peritonitis.

Since 1892, when Bier brought this method before the German Surgical Congress, it has been extensively used in Kiel and elsewhere, and it has been employed at Breslau since the beginning of 1893 in combination with the application of iodoform as already described. The object is to produce venous congestion. It is not clear how the beneficial change is brought about, but that such does take place there seems to be no room for doubt. The limb is first bandaged firmly within a few inches of the joint. Above the affected joint a rubber tube or bandage is then wound sufficiently tightly to produce a distinct bluish-red discoloration of the skin of the unsupported parts below.

In some patients the full amount of congestion can be easily borne from the first, in others it must be begun gradually and increased as the patient gets used to it. The congestion may be maintained for from fourteen to eighteen hours out of the twenty-four, and the remaining time may be employed to get rid of the edema by the use of elastic pressure applied over the joint itself. As the condition improves, the length of time during which the congestion is kept up may be diminished by degrees. To prevent ill effects from the pressure of the elastic bandage, its position should be frequently altered and an ordinary bandage should be applied between the skin and the rubber.

In the parts of the limbs where the venous congestion is applicable—i.e., below the hip or shoulder—this method and fixation (or attempted improvement of the position of the joint) constitute the first stage of the treatment; and this is continued for from eight to fourteen days. Then from six to ten cubic centimeters of the emulsion for children and from fifteen to thirty cubic centimeters for adults is injected into and round about the joint. Abscesses, however, are injected straight away if the diagnosis is clear and their position suitable.

The intervals at which the injections are to be repeated have already been mentioned. During the longer intervals the patient may be sent home or to some health resort, but all the time the venous congestion should be maintained. When a fair trial of conservative treatment has been given without definite
improvement, operative measures will require to be undertaken; but the experience in Professor Mikulicz's clinic has been that the operations, since these conservative methods have been in use, have not only been much fewer, but also much less serious. This conservative treatment has established itself more and more firmly in favor as time has gone on. The actual number of cures by its use is equal to that attained by the ordinary operative methods, while the functional results which it gives are decidedly better and the mortality is less. Only in adults, with a fixed patella, is primary excision preferred to the conservative measures which have just been indicated.

POSTERIOR MEDIASTINITIS CURED BY OPERATION.

Heidenheim (Centralblatt f. Chirurgie, No. 27, 1899) reports the case of a workman operated on because of an abscess of the posterior mediastinum at about the height of the aortic arch. This patient had swallowed a bone a year and a half before, and for two weeks after this complained of pain in swallowing. When he was first seen by the reporter he had not been able to swallow anything for five days, and had suffered from a swelling above the right clavicle for fourteen days. Moreover, there were symptoms of septic absorption, irritability of the heart, and violent pains in the chest. The supraclavicular fossa was almost completely obliterated by an edematous swelling.

A transverse incision was made just above and parallel to the clavicle, and the clavicular insertion of the sternomastoid muscle was divided. The tissues were markedly edematous. An opening was then made by blunt dissection outward and backward toward the spinal column and esophagus. A mass of foul, necrotic connective tissue was found surrounding, at a depth of about three inches outward and backward from the sternoclavicular articulation, a collection of pus. The wound was packed, and healed without complication.

The examination of frozen sections shows that just above the jugulum, and at the level of the first dorsal vertebra, there is a considerable area of loose connective tissue to either side of the esophagus, somewhat broader on the left than on the right side. It has lying behind it the bodies of the vertebrae. The approach to this loose connective tissue is an easy one. After division of the clavicular end of the sternomastoid muscle, by working backward from a point just above the sternoclavicular articulation, this space is reached on the right side through the comparatively wide interval lying behind the jugular vein and carotid artery. It is by this route that pus formed in the posterior mediastinum may reach the supraclavicular fossa.

Carazcini opened such an abscess which formed at the level of the sixth and seventh dorsal vertebrae. He preferred, however, to reach the pus by dorsal incision. The dorsal route is a comparatively simple one, provided the transverse processes of one or more vertebrae are divided at their bases together with the central portion of the ribs attached to the vertebrae. Thus all danger of wounding the pleura is avoided, and hence this method is better than simple resection of a portion of the rib with subsequent thrusting of the pleura to one side.

RUBBER GLOVES OR GAUNTLETS.

Summers (Journal of the American Medical Association, July 8, 1899) urges the habitual use of sterilized rubber gloves or gauntlets after cleansing the hands by some good method.

It should be the rule: (1) In obstetric practice; (2) in operating on all forms of septic cases; (3) in the examination and treatment of all forms of septic infectious diseases, such as erysipelas, septiciemia, and pyemia, in which the hands come in contact with primary or secondary foci of infection — and this rule applies to the nurse also; (4) in operating on clean cases soon after operations on infected ones; (5) in abdominal sections following vaginal operations on the same individual, this may be reversed, wearing the gloves during the vaginal work, and taking the gloves off or donning a fresh pair before beginning the abdominal work; (6) in examining fresh wounds after recent examinations of or operations on dirty cases; (7) in all forms of rectal surgery.

It is a matter of choice under other circumstances whether or not gloves be worn. However, there is no question that there is less danger of infection where gloves are worn than when reliance is placed in an attempted sterilization of the naked hands. We have the testimony of two good American surgeons, Halsted of Johns Hopkins and McBurney of New York, as to the truth of the lessened dangers of infection when sterilized rubber gloves are worn by all persons.
taking part in the conduct of a surgical operation. Many American and European surgeons now use rubber gloves.

An impervious cotton glove is perhaps quite as good as the rubber article—the ordinary glove is not safe. The author states that during the six months he has been using rubber gauntlets in his work, the results have been more gratifying than formerly. Occasionally he has felt compelled to take off the gloves in order to carry out some technique more satisfactorily, but such acts seldom occur now. There is little difference in tactile sensibility between the naked fingers and those covered with a well-fitted, good-article rubber glove. The advantages outweigh the possible, in rare instances, lessened tactile acuteness. One dozen pairs of the best quality can be bought for fifteen dollars. Sterilized glycerin may be used to lubricate the hands before drawing on the gloves. A glove that cannot be reasonably easily drawn over the hand after filling it with sterile water is too small. Vaselin or grease ruins the rubber. The gloves should be either boiled or wrapped in a towel and placed in a steam sterilizer. Lastly, rubber gloves are a protection to the physician and surgeon against infection.

A PLASTIC OPERATION DESIGNED TO SUBSTITUTE, FOR THE SPHINCTER ANI, THE LEVATOR AND THE GLUTEAL MUSCLES.

Lennander (Centralblatt f. Chirurgie, No. 25, 1899) had brought to him a patient suffering from incontinence of the feces, as a sequel of a severe phlegmonous process which had entirely destroyed the anal sphincter. For the purpose of remedying this disability, the following operation was performed: A cut was made in the middle line, traversing the under half of the sacrum and the coccyx. From the point of this bone it was carried in a curve to either side, the convexity of which touched the tubera ischiil. The two gluteal muscles were freed from the sacrum, and from the sacroischial ligament. To a point corresponding to the upper half of this ligament these muscular flaps were still further freed by an inch and a half incision running from the sacrum in the direction of the muscular fibers. The scar tissue, which was placed about the posterior portion of the rectum, was, together with the raphe of the anal perineum, dissected from the point of the coccyx. The levator ani and coccygeal muscle were then exposed and were divided by a transverse cut reaching almost completely across the pelvis, yet so planned that the arcus tendineus of the levators was not too nearly approached, thus avoiding injury to the nerves which supply these muscles. The levator ani could not be separated from the coccygeous without dividing the inner layer of the pelvic fascia. The levators were drawn forward against the rectum, secured in this position by four catgut sutures placed in the middle line. The defect in the pelvic diaphragm resulting from this transposition was then closed by drawing the two gluteal muscles, which had previously been dissected loose, forward as far as the anus, and fastening them in this position by heavy catgut sutures; uniting them first each to the other, then to the levator ani, and finally to the periostium of the coccyx. Two drainage-tubes were inserted under the gluteal muscles. The anal aperture was kept closed by sutures during the operation.

The wound suppurred freely. In spite of this the ultimate result was an extremely good one. The muscles were regularly exercised by means of the galvanic current and by voluntary efforts upon the part of the patient to retain enemata.

The author believes that this method of operating may be serviceable in relieving the incontinence which frequently follows cancer operations.

LAPAROTOMY FOR PERFORATED ENTERIC ULCER.

Dalziel (Scottish Medical and Surgical Journal, July, 1899) states that about four per cent of enteric cases admitted to Belvidere Fever Hospital, Glasgow, die from perforation. During the last few years Dalziel has operated on eight cases of perforated enteric ulcer. Three were so advanced in general peritonitis that they were utterly hopeless; nor would he again operate in similar cases. Of the remaining five, one made a complete recovery; one promised well, but died the day after operation from intestinal hemorrhage; one lived three and a half days; while the other two continued to sink after operating, and though relieved from much suffering, died in about the usual interval after perforation.

The prognosis for operation depends upon the early diagnosis of perforation, on the stage of the fever, on the severity of the fever and condition of the patient, and on the nature of the peritoneal infection.
The first of these alone is under the control of those in charge of the case, and it would appear that it is a matter of some difficulty to arrive at an early and accurate diagnosis; nor is this to be wondered at, since the diagnosis depends on the phenomena of peritoneal irritation, so apt to be masked by the general toxemia attending the fever, or originated without any gross perforation at all. The usual classical symptoms, initiated by acute abdominal pain, often attended by a sudden cry, vomiting, the rise and perhaps, if in the acute stage of the fever, a sudden temporary fall in the temperature, the rapid increase in the pulse-rate, the rigid abdominal muscles, with flattening of the abdomen, soon followed by distention from tympanitis, and later from the accumulation of peritoneal effusion, the distressed thoracic breathing, the pinched features and anxious, terrorized look, no doubt form a clinical picture which cannot be mistaken; but when the picture is complete, and the diagnosis certain, it is generally too late for surgical interference to be of any avail.

After about twelve hours the peritoneal infection has become so extensive and profound that little hope can be entertained of so cleansing it that its phagocytic power, enormously great as it is, may overcome the microbial infection. Every hour that passes increases the gravity of the prognosis with the ratio of microbial multiplication. No doubt the "twelfth hour" will be reached at different times in individual cases according to the nature and amount of the initial infection, as for example whether it be the bacillus coli commune, a streptococcus, the mere chemical irritation of the intestinal contents, with absence or at least a very minimum amount of microbial growth. As a matter of fact, in some cases which have recovered no microorganisms were found in cultures made from the peritoneum twenty-four hours after the operation. The more aseptic the intestinal canal can be kept, the better the prognosis after surgical interference. The typhoid bacillus seems to play a small part in the peritoneal mischief, and has not been found in the free fluid from the peritoneal cavity.

It is necessary, then, to consider what symptoms may be relied on to warrant early diagnosis and operative interference. The symptoms of abdominal pain and tenderness developing suddenly in or near the third week of the disease must be looked on as of serious import.

Tenderness on pressure is usually found to the right of and below the umbilicus, near McBurney's point in appendix perforation, and in the iliac fossa and flank in cecal perforation. While in acute cases there may be considerable tenderness throughout the illness, it must be looked upon with grave suspicion if it occurs suddenly late in the affection, and should suggest the involvement of the serous covering of the bowel in the inflammatory process, or an actual perforation which may either form gradually, as in the case of a perforating ulcer of the stomach and as especially happens late in the disease after the fall of temperature, or suddenly from a gross slough of the base of the ulcer. Clearly tenderness may be due to a localized peritonitis over an ulcer, and this strengthened by deposit of lymph or formation of adhesions to surrounding parts may spontaneously recover or pass on to perforation. It is to be noted, as accentuated by Frank Gairdner in his monograph "Peritonitis in Enteric Fever," that a local peritonitis initiated without perforation may extend, become general, and kill the patient. This stage of localized peritonitis might well be termed the "preperforative stage," were it not that it is not necessarily followed by actual perforation. It ought, however, to induce extreme vigilance on the part of the physician, and probably his association in the case with a surgeon.

Actual perforation generally occasions pain so great as to make the patient cry out. The muscles overlaying the rupture become rigid. Sudden alterations of temperature are common. There is vomiting, probably only in one act, to be resumed in the later stages of the peritonitis as a continuous and distressing symptom. The pulse gets more rapid in every case, and very soon after perforation may increase in frequency with alarming rapidity.

In the preperforative stage the increase in pulse-rate may be comparatively slight, as from ten to fifteen beats per minute, and this with the other mild symptoms may, with the coating of protective lymph or formation of adhesions, lull the observers into a false security. The author states that in nearly all his cases the symptoms of the preperforative stage have been well marked. The symptoms are not peculiar to enteric ulcer perforations, but may be equally well marked in ordinary appendix ulcerations, and, as pointed out by Cushing, in dysenteric ulcerations as well.
Applying the principles which guide surgeons in cases of perforative peritonitis other than enteric, surely no one cares now to wait till the appendix has perforated in a case where there is good ground to fear it.

There remains, however, one symptom of which the author states he regrets he has had too little practical experience, but which seems worthy of careful elaboration, namely, leucocytosis, to which much attention has lately been paid, especially in the Johns Hopkins Hospital, by Thayer, and concerning which the following conclusions have been drawn by Dr. Harvey Cushing, in his excellent monograph on enteric perforations:

1. The appearance of leucocytosis in the course of typhoid fever points towards some inflammatory complications in the early stage.

2. If the complication be a peritonitis and remains localized, associated with a preperforative stage of ulceration or with a circumscribed slowly-forming peritonitis after perforation, it may be, and usually is, signalized by an increase of leucocytosis in the peripheral circulation.

If, however, a general septic peritonitis follows, the leucocytosis may be transitory and overlooked, as it disappears concomitantly with the great outpouring of leucocytosis into the general cavity.

Accurate early diagnosis is not a simple matter, and, bearing in mind the disaster in delay, it seems a wise course if in doubt to operate.

All of these cases are repeated at more or less length. There have now been over eighty cases recorded as recovering after enteric perforation; and while not a few proved to be localized by previous adhesions, the great proportion of them were perforations opening into the free peritoneal cavity. Later statistics indicate twenty-five per cent of recoveries after operation, and this, Dalziel believes, is a reasonable estimate.

The operation is usually a very simple one. The perforation can in ninety per cent be found without any difficulty, and with very slight exposure of the bowel. No blood is lost and no important structure is cut, and the patients bear what slight operative interference is required remarkably well. An incision two to three inches in length in the middle line below the umbilicus gives sufficient entry to the field of operation, and is indeed directly over the portion of the bowel most frequently affected. In three of Dalziel's eight cases the perforation was found in the first loop of the bowel presenting in the wound. In the others it was readily found by tracing the ileum upwards till the perforation was seen. The suturing of the gut is early accomplished by two rows of continuous fine silk sutures, carried beyond the margins of the ulcer.

---

**INFLAMMATION OF THE HIP BURSÆ.**

ZULZER (Deutsche Zeitschrift für Chirurgie, Badn. L.), on the basis of a case which led to repeatedly mistaken diagnosis, contributes a profitable study of the inflammations of the bursæ placed about the hip-joint. Inflammations of these bursæ are comparatively rare; and it is, perhaps, mainly because of this that when they are encountered a mistake is common. The two bursæ of chief clinical interest are the one placed beneath the iliopsoas muscle and the one lying beneath the gluteus maximus over the greater trochanter. Hydromata, cysts, and abscesses may occur in either of these bursæ.

A collection of sixty cases made by the author shows that fourteen were subiliac and the rest trochanteric.

The subiliac is placed below Poupart's ligament and beneath the iliopsoas muscle. When this bursa becomes inflamed and swells, the tumor may reach large dimensions, extending even as far as the middle third of the thigh. A smooth, tender, usually fluctuating tumor develops, often accompanied by pain along the course of the crural nerve, and sometimes complicated by symptoms of pressure upon the large vessels. There is some interference of motion, and occasional fixation. The leg is usually held in abduction, slight outward rotation, and moderate reflexion.

The disease is distinguished from coxitis by the absence of shortening, by the fact that the great trochanter is in its normal position, and by the absence of tenderness in the hip-joint. Injury is usually the cause of inflammation, though exceptionally rheumatism, syphilis, or gonorrhea may cause a bursa in this region. The disease is extremely chronic.

Trochanteric bursitis is characterized by much the same symptoms, except that it may be confused not only with coxitis, but with periarticular abscesses, or inflammation of the trochanter itself. The trochanteric bursa frequently becomes tuberculous.

The treatment should be radical, the entire sac being dissected out.
OPERATION FOR CLUBFOOT.

Schanz (Centralblatt für Chirurgie, No. 25, 1899) calls attention to the frequency with which the desired result is not attained after a very thorough series of operations for the remedy of the deformity and disability incident to clubfoot. Even though the patient treads upon the sole of the foot when the deformity is corrected, there is a permanent adduction of the anterior part of the foot and a shortening of the plantar fascia. To prevent this, he urges that the tendo Achillis should not be cut until the adduction and the contraction of the plantar fascia have been entirely overcome. The first operation divides all the structures which interfere with the proper position of the foot, excepting the tendo Achillis. A plaster of Paris bandage is put on, the patient is encouraged to walk, and four to six weeks later the tendo Achillis is cut.

OINTMENTS AND PASTES.

Wende (American Medical Quarterly, June, 1899), holding that a careful selection of local remedies is of greater significance than a well directed constitutional administration of drugs, gives an admirable outline of the principles on which ointments should be compounded. Anhydrous lanolin he prefers as a basis.

Pastes, during the last few years, have been largely used in the treatment of skin affections, especially for the various types of eczema. They were first introduced to the notice of the profession by Lassar and Unna, of Germany. They are applications which resemble ointments, having a firmer consistence, however, due to a powder incorporated in an unusual proportion. The substances used may be either of a mineral or vegetable origin. The minerals generally employed are kaolin, talc, bolus alba, chalk, zinc oxide, calcium, and magnesium carbonate, while those taken from the vegetable world are usually starch and lycopodium.

The advantages over ointments are twofold. They not only defend the eruption from external irritation, exclude the air, preventing desiccation and oxidation, but the excretions and secretions of the diseased parts, through their influence, are also absorbed. Furthermore, they aid adhesion, producing a fixation of medicaments. These preparations employed for local application in the treatment of skin diseases are either of a hard or soft consistence, the former containing more or less gelatin.

One of the best known and useful belonging to this class is the so-called Unna's gelatin paste, made by the combination of:

- Zinc oxide,
  Gelatin, 7.50;
  Glycerin, 15.00;
  Aqua destill., 20.00.

This forms a basis in which may be incorporated iodoform, salicylic acid, ichthyl, chrysarobin, thiol, or other antiseptics, to meet the indications of the case. It is beneficial in overcoming the evils engendered in subacute and chronic eczema and like inflammatory processes.

However, it is contraindicated in very hot climates, owing to its limitation, preventing solidification; nor is its application adapted to hairy parts, as its removal then would be painful. As a practical suggestion in its use before it has become hardened or set, it would be advantageous to gently pat it with absorbent cotton or cover it with a thin layer of cheese-cloth in order to prevent the undergarments from adhering to it.

Of the soft pastes, the one that has enjoyed the best reputation is that first prescribed by Oscar Lassar, and named after him. It consists of:

- Acid salicylici, 2.00;
- Zinc oxidi,
- Amyl,
- Vaselin,
- Lanolins anhydr., 20.00.

Misc. Leniter lerenda fiat pasta.

This exceedingly useful therapeutic preparation is of extensive applicability, notably in the different forms of eczema. It is applied like an ointment, spread on the skin, leaving a coating on it and absorbing secretion instead of sealing it up.

Other remedies, as tar, beta- and hydronaphthol, ichthyl, etc., may be profitably combined. A gum paste is a modification of the soft variety, in that it contains gum arabic. This mixture should be carefully prepared without the aid of heat, and consists usually of some particular powder in the proportion of two parts to one of mucilage of acacia and one of glycerin.

Chrysarobin and pyrogallol should not be added to gum pastes. Fatty and soapy substances, if commingled in large amounts with these pastes, injure their special properties.

Their mode of application is a matter for attention and of importance. They should be gently rubbed upon the diseased part with the fingers or an appropriate spatula, th...
former being used when the skin is tender. They should be well introduced into all cracks and crevices, and uniformly distributed in a moderately thick layer over the whole of the affected epidermis in order that the physiological and therapeutic properties possessed by the paste may be justly fulfilled.

THE VALUE OF THE DIFFERENT METHODS OF BOWEL UNION.

Fowler (Annals of Surgery, July, 1899) has abstracted an article by Chlumsky (Centralblatt für Chirurgie, 1899, ii) based on an experimental investigation on dogs and human cadavers. The tests were made by means of hygrometric pressure.

In the human bowel the intact intestinal wall alongside of the anastomosis was torn earlier than the site of the anastomosis itself. Recent intestinal unions in dogs, applied in the living animal and examined at once, appeared to be less resistant than those in the bowel of the dead dog.

The firmness of the intestinal anastomosis applied in the living dog diminished continuously for the first four days. During the first twenty-four hours it diminished only moderately, unless the peritoneal inflammation due to the operation was very severe at the site of the anastomosis and its neighborhood (100 to 200 millimeters hygrometrically); if the loops of anastomosis were markedly reddened or otherwise considerably altered, the firmness of the anastomosis diminished surprisingly after twenty-four hours (20 to 100 millimeters hygrometrically); forty-eight hours following operation, in case of slight inflammatory reaction, the resistance was still less (80 to 120 millimeters hygrometrically), and diminished still more during the next twenty-four hours. On the third and fourth twenty-four hours, the lowest resistance was regularly reached (50 to 90 millimeters hygrometrically).

On the fifth day the resistance to pressure increased (50 to 120 millimeters hygrometrically), and on the seventh day increased to the resistance of the recent anastomosis (150 to 340 millimeters hygrometrically). Twenty-four days following, the original resistance was increased (250 to 350 millimeters hygrometrically).

Ten days following operation, the intact bowel tore before the site of anastomosis gave way (height of pressure 380 to 400 millimeters hygrometrically); and on the fifteenth day in only one case did the anastomosis tear before the uninjured bowel wall. Thirty days after operation, and in one case 120 days after, the resistance of the site of anastomosis and the bowel wall was nearly equal.

At first sight it is surprising that such low pressure will tear the anastomosis between the third and fifth day. One would imagine that the solidity of the anastomosis would steadily increase. This can be readily explained. During the first two days the parts are fixed mechanically by the suture or button. The parts gradually become infiltrated and consequently less resistant, thus offering a less secure hold for the fixing elements. Every operator knows what small resistance most tissues possess two to five days after a trauma. In the intestinal wall the conditions are similar.

Further, anastomosis by button did not differ materially from anastomosis by suture; either was torn by approximately the same amount of pressure. In case of simple mechanical traction the anastomosis by button gave way earlier, especially when the button was cast off or absorbed before the fifth day. Attention is drawn to the fact that in certain cases in which the Murphy button was used, even in cases of recent anastomosis, while the anastomosis gave way sufficiently to allow the button to show, yet no fluid escaped for some time after. This is accounted for by the integrity of the purse-string suture fastening the intestinal wall to the button.

As a general rule, however, circular anastomosis stood a higher pressure than lateral. In recent anastomosis, done by suturing, the site of rupture was almost always at the point where the knot of the continuous suture lay. This was particularly so if two knots lay together. If the continuous sutures were first tied separately and then together the perforation was always at this point.

All the anastomoses were exceedingly fragile from the third to the fifth day. In two cases, in spite of the greatest care, the anastomosis was torn before the manometer examination. Adhesions to neighboring structures, especially to omentum, were regularly present. During the first few days the site of anastomosis was found almost entirely encircled by portions of the greater omentum. Later, after weeks and months, these adhesions were less numerous, but in only two cases were they entirely absent. In one case, the serous surface being scarified after Wölfier’s method, the adhesions were so nu-
merous that it was extremely difficult to identify the site of anastomosis. Anastomoses the seat of adhesions withstood a higher pressure than those not so supported. In one case a small flap of the greater omentum around the site of a button was sutured, with excellent result.

In regard to button methods, the results were not so favorable. Chlumsky concludes that a button must stay in a dog’s bowel at least five days, protecting the site of anastomosis in a purely mechanical manner; if left longer than a week it is apt to cause necrosis. In one case a Murphy button passed per anum three days following its application—that is, at a time when its presence was most essential. In another case it caused perforation on the third day. The result with decalcified bone button was still more unsatisfactory. All of these absorbable buttons, particularly Frank’s, were absorbed early, or soon passed in a half-digested condition. Hardening or partial decalcification afforded but slight improvement.

In two children, the subjects of gastric fistulae, because of stenosis of the esophagus due to potash burns, the author had the opportunity afforded of introducing into their stomachs small undecalcified bone olives. These were in a stage of advanced digestion after two or three days. Decalcified bone olives, left in the same time, became as soft as butter. In the colon, however, they remained unaltered for from seven to ten days.

THE IMPORTANCE OF BLOOD EXAMINATIONS IN REFERENCE TO GENERAL ANESTHETIZATION AND OPERATIVE PROCEDURES.

Fish (Annals of Surgery, July, 1899), who is profoundly impressed by the dangers incident to anesthetization, contends that a solution of the problem of safety in anesthesia can be attained only in the laboratory.

In the blood we have a gauge, the readings of which give us a fairly accurate insight into our patient’s general condition. While being of the greatest diagnostic and prognostic value, it acquaints one with conditions operable and inoperable. If the cases are inoperable, so far as the resistance and reactionary powers of the individuals are concerned, it shows by a regenerative treatment when they become operable or when operative procedures should be refrained from altogether.

Neurasthenics, anemics, chlorotics, leuemics, and those of a so-called lymphatic temperament, withstand general anesthetizations and operations poorly, and in all these the blood shows marked changes from the normal, which is believed to account for the difficulties and dangers attendant upon operative procedures in these individuals.

It is imperative that a routine practice of blood examinations should be instituted by surgeons and by interns of surgical hospitals in conjunction with the methods established, giving us thereby absolute indications for palliative or radical treatment.

The specimen of blood to be examined is taken from the lobe of the ear or finger-tip by a small puncture, after thoroughly washing with soap and hot water, and is then examined for—

1. Its specific gravity by Hammerschlag’s method.
2. Its reaction by the method of Leibreich.
3. Its absolute and relative number of red and white corpuscles by the Thoma-Heiss counter; also the shape, size, and color of the former, and the varieties and staining properties of the latter.
4. Its hemoglobin percentage, as given by the instrument of von Fleischl.

The specific gravity indicates grossly pathological conditions of the blood elements, and gives us a fairly accurate estimate of the hemoglobin percentage.

The reaction is important from the fact that individuals whose blood shows a decrease in alkalinity withstand general anesthetizations and operations poorly.

The number and characteristics of leucocytes are of the utmost importance from a diagnostic and prognostic standpoint; for, besides influencing to a greater or less extent the production of safe anesthesia, they also indicate with accuracy when to and when not to operate in certain cases, as is shown by the following:

1. Infection, mild; resistance, good; small leucocytosis.
2. Infection, less mild; resistance, less good; moderate leucocytosis.
3. Infection, severe; resistance, good; very marked leucocytosis.
4. Infection, severe; resistance, poor; no leucocytosis.

The above can be surgically interpreted into: (a) When to employ palliative means of treatment; (b) when to consider operative intervention; (c) when to operate; (d) when not to operate.

In individuals whose blood presents a
hemoglobin percentage of fifty or less, the anesthetic vapor produces quickly an increased pathological condition by a forced abstraction of oxygen from a tissue ill-conditioned to part with it; or, the hemoglobin percentage being so small, the compound resulting from the anesthetic vapors controls its ability to take up the requisite amount of oxygen and imparts it to the tissues as under normal conditions. Hence it is not surprising that these individuals show quickly signs of collapse. Besides certain nervous forces, respiration is dependent upon the amount of hemoglobin contained in the blood, and if this is reduced beyond a certain limit, respiration must cease. The minimum is apparently twenty per cent, as in three cases dying of collapse after operation Mikulicz found only fifteen per cent remaining.

A safe rule to follow is, never produce a general anesthetization in an individual whose blood shows a hemoglobin percentage of less than fifty.

Safe anesthesia is dependent upon, first, the percentage of hemoglobin in the blood before, during, and after anesthetization; and secondly, a normal or increased number of the polynuclear neutrophiles. Anesthetic vapors may be inhaled with impunity just so long as the hemoglobin percentage remains higher than the physiological requirements of the system, and the phagocytic or reactionary powers of the polynuclear neutrophiles are not overcome by the anesthetic compound.

Oligochromemia, from whatever cause, should invariably be considered as a contraindication for the administration of a general anesthetic for diagnostic or operative purposes.

OBSERVATIONS UPON VOLVULUS, WITH REPORT OF THREE CASES SUBMITTED TO OPERATION.

ELIOT (Annals of Surgery, July, 1899) has operated upon three cases of obstruction of the bowels, due to volvulus. In one case the operation had to be repeated twice for the relief of recurrence. One case died.

In all cases where volvulus is suspected a rectal examination should invariably be made. If the sigmoid is twisted, the introduction of a sufficiently small hand and forearm will detect the obstruction. As this instrument of examination is not usually available, the capacity of the gut below the obstruction should be determined by the injection of water, and by this means it is found that a relatively small amount only can be introduced, and, after being retained for a short time, is more forcibly expelled than normally is the case.

In the rarer enteric variety, the application of this test yields a negative result.

The examination of the abdominal wall is more satisfactory, when conducted after complete anesthesia has been established. Even before this is done, inspection sometimes reveals a condition of local asymmetry due to the distention of the affected loop.

By palpation the distended, elastic, and resistant arms of the twisted loop may be mapped out quite accurately on the abdominal wall, especially when muscular relaxation has followed the administration of the anesthetic. In cases of marked constriction, the paralysis of the affected loops renders them immovable and fixed, so that their position in the abdominal cavity is a constant one. Percussion should be conjoined with auscultation. The area of tympany thus obtained corresponds to the position of the elastic, distended loops.

The treatment of volvulus is both palliative and radical. In a small percentage of cases spontaneous reduction can take place through peristaltic activity alone. This can be occasionally accomplished by the effort of the surgeon. For this purpose reduction may be favored by the inversion of the patient. This neutralizes whatever effect gravity may have had in the production of the difficulty.

When the sigmoid is involved, the use of rectal injections may result in reduction. Eliot notes one case in which intrarectal manipulation by a diminutive hand failed to untwist the gut. This is a measure, however, that might easily succeed in those cases in which the volvulus is of recent formation.

The trial of any palliative measure should not be allowed to consume any considerable length of time, and should be immediately followed in the event of failure by laparotomy.

If an accurate diagnosis has been made, the abdominal cavity may be opened in that part immediately overlying the affected loop. If, on the other hand, the diagnosis is uncertain, the median incision is preferable, as it allows a rapid examination of the abdominal contents, an accurate diagnosis of the nature of the difficulty, and usually through it the particular method of treatment indicated may be satisfactorily carried out. If the affected loop cannot be easily
reached through such an incision, a second lateral one may be quickly made without subjecting the patient to any additional risk, and without causing any increased weakness of the abdominal wall, in the event of ultimate recovery. This method of procedure is indicated particularly in those cases of volvulus of weeks' duration, which resemble obstruction by obturation, especially carcinoma; and in this latter condition, when the sigmoid is involved, the first evidence of the existence of the trouble not infrequently consists in the development of symptoms of acute obstruction. Two such cases, in fact, have come under the writer's attention. To distinguish accurately between these two conditions is particularly important, because in each group of cases the appropriate treatment is entirely different. In carcinoma an artificial anus gives relief; in volvulus, nine cases reported in the literature of the subject, so treated, proved fatal without exception.

With the opening of the abdominal cavity it is absolutely essential in every case to accomplish the reduction of the volvulus by manipulation. This should be gently employed, as laceration of the gut at the point where the two limbs cross has taken place during efforts of reduction.

If the gut proves viable, measures should be taken to prevent the recurrence of the volvulus, provided that the general condition of the patient does not contraindicate this procedure. To attain this end the entire sigmoid flexure has been resected with success, the divided ends being brought together by end-to-end anastomosis. In three such cases one promptly died; one died a month after the operation of septic pneumonia, the peritoneal cavity and sutured gut being found, on autopsy, in a normal condition; and the third recovered. This method of treatment seems ultra-radical and dangerous, when simple measures will accomplish the same purpose. It is always difficult in such cases to determine the exact amount of gut which it is proper to remove, and the divided ends, having been at any rate moderately congested before the operation, do not unite with the same degree of certainty as in those cases of resection where no impairment of circulation has previously existed.

Senn recommends the shortening of the mesosigmoid by passing through it successive rows of sutures. It is doubtful whether this is of any practical utility.

The best plan of procedure seems to be the passing of interrupted catgut or silk sutures between the serous coat of the gut and the anterior parietal peritoneum. In those cases in which the constriction has caused death of the gut, the necrotic portion should be removed, and the divided ends brought into the angles of the wound to be united subsequently, when the patient's general strength has been restored.

ON MOVABLE KIDNEY.

Wallace (Scottish Medical and Surgical Journal; quoted from Journal of Cutaneous and Genito-Urinary Diseases, July, 1899) believes post-mortem statistics of mobility to be fallacious, as the kidney is more fixed after death than during life, and that no satisfactory explanation has been given either of the reason for the greater frequency of the occurrence on the right side as compared with the left, or of the causes which lead to kidney mobility. The theory that it is more common in women of the poorer classes, who have borne many children at short intervals, the observations of several authors have failed to substantiate, and in his own cases requiring treatment—fourteen in number—thirteen were females, and of these seven were nulliparous, and only one of the others had borne several children and belonged to the poorer classes.

The loss of fat, supposed to be a predisposing cause, the author is inclined to believe to be in reality the result, as it certainly is in the cases with gastrointestinal symptoms. The condition comes on gradually in the majority of cases and gets progressively worse, and the exact time of onset is rarely known, unless due to traumatism.

When palpating the lumbar region for the kidney it may fail to be found, because at the time of examination it may be low down in the iliac fossa—a source of error to be borne in mind.

Clinically, the symptoms are grouped under four heads: (1) Simple mobility without symptoms; (2) pain, described as a sensation of aching and dragging, on the affected side; (3) renal pain, which may be accompanied by hematuria, pyuria, or intermittent hydronephrosis, but not necessarily so; (4) the gastrointestinal disturbances accompanied by, or ending in, neurasthenia. The symptoms, however, are not always commensurate to the mobility.

The affected kidney is usually healthy, and the symptoms, as a rule, wholly subside after fixation of the kidney.
The author accepts Kendall Frank's explanation of symptoms: (1) Some symptoms are common to both kidneys, as the dragging pain, sense of weight, neuralgic pains, fatigue, and debility; (2) some symptoms belong exclusively to mobility of the right kidney, the gastric crises, indigestion, flatulence, vomiting, and pain, which come on about two hours after eating. The symptoms peculiar to the left kidney are not pointed out.

With regard to treatment three classes are to be recognized: (1) Those in which no treatment is necessary, the condition being discovered by accident; (2) those relieved by the wearing of a pad; (3) those requiring operation—nephropexy. For a pad, the author prefers an air-pad, fixed to the corset, and put in position while the kidney is known to be in place.

CURE OF VERY GRAVE ACCIDENTS IN TWO PROSTATICS BY CATHETERIZATION.

Both cases were grave. One had urinary intoxication with high fever, the other severe bladder hemorrhage. In both, especially in the latter case, cystotomy was proposed, and decided upon as urgent; nevertheless, simple catheterizations properly applied sufficed to relieve the gravity of the situation.

The first patient, eighty-one years old, had used the catheter for ten years, without any precautionary procedures. His urine had been infected for a long time. There was a residue of a pint of urine after spontaneous urination. At night the patient used the catheter two or three times. The urine was very purulent, a colon-bacillus infection, with evidence of pyonephrosis. He had thirst, dry tongue, anorexia, insomnia, itching of the skin, and gradual onset of fever, mounting to 102.5° F., with marked oscillations, and rapid loss of flesh. Under the catheter, d demeure, which was changed every third day, there was gradual improvement, but a purulent urethritis set in, followed by a discharge of pus, apparently due to prostatic abscess. After this occurrence improvement again set in, and by lavage and internal catheterization all symptoms cleared, though the urine remained purulent; but the patient was able to resume his former life.

The second patient, seventy-six years old, had suffered for several years from prostatic enlargement. When first seen he had a purulent residual urine and a very large prostate. Daily catheterization and lavage were advised, under which he did well for several months. Then he began to have severe vesical pain and frequent urination, and a sense of weight. One day a large quantity of blood followed catheterization, which, in spite of treatment, recurred with severity each day, and a tumor was suspected. Cystoscopy was impossible, and the patient entered the hospital for operation. Pending the operation, regular catheterization was instituted every two hours, and the urine withdrawn was replaced each time by an equal amount of boric solution. Under this régime the hemorrhage ceased, and the same procedure was continued for one week. The hemorrhages did not return, the bladder cramps disappeared, and the patient improved. Complete catheterization was then performed, and the intervals lengthened, and light lavage of silver nitrate was made. The urine became clearer. In three weeks the catheterizations were made morning, night, and in the middle of the night; then only twice a day; and the patient began to urinate spontaneously. He was then allowed to return home, and to again catheterize himself.

According to Janet, catheterization is the operation of choice in the retention of prostates, even in the grave accidents which complicate it.

DIAGNOSIS AND TREATMENT OF DIFFUSE SEPTIC PERITONITIS, FOLLOWING PERFORATING DUODENAL ULCER.

Schwartz (Bulletin et Mémoire de la Soc. de Chir. de Paris, xxiv; quoted from the Brooklyn Medical Journal, July, 1899) briefly reports four fatal cases of perforating duodenal ulcer, communicated to him by Rochard, Gumiard, Sieur, and Loison. The first of these authors treated the perforation by laparotomy, without result. In the discussion on diagnosis and treatment, Collin's investigations (conducted under Letulle's direction) are quoted. In 262 cases collected, the distance between the ulcer and the pylorus was less than two inches in 242 cases—i.e., was in the upper third of the duodenum. In 85.6 per cent there was a single ulcer; in twenty-six cases two ulcers; in three cases three ulcers; in four cases five
ulcers. The usual site is on the anterior duodenal wall. Duodenal ulcers are far more likely to perforate than ulcers of the stomach. Collin concludes that sixty-nine per cent perforate. In the majority of cases perforation took place directly into the peritoneal cavity; these did not present marked symptoms of disease previous to perforation. In only five cases out of twenty-five collected by Schwartz was any disease diagnosticated previous to perforation—one as dyspepsia, two as gastric ulcer, and two as simple gastralgia.

Pain is a constant symptom, is intense, and is located in half the cases below the right costal arch or in the epigastrum; rarely on the left side. Prostration is rapid. Temperature is usually low, rarely above 100° F. The pulse is markedly accelerated. Vomiting is often absent at the onset, and may not appear for forty-eight hours. There is rapidly increasing rigidity of the abdominal muscles, which prevents palpation of the abdominal viscera. Percussion gives tympany in place of normal liver dulness. Intestinal obstruction is present.

A correct diagnosis was made in a very small proportion of cases, obstruction or appendicitis being diagnosed. The incorrect diagnosis usually resulted in delayed operation. Only three out of twenty-five cases operated upon resulted in recovery, and in only one of the three was recovery permanent. One of these succumbed two months later to ileus, due to adhesions, and the other to a second duodenal perforation six months after operation.

Schwartz advocates early exploratory laparotomy and suture of the perforation. Frequently the greatest collection of pus in diffuse septic peritonitis is in the right iliac fossa and below the liver. If indubitable evidence of disease of the appendix is not present, a further search must be made for the site of perforation.

In the discussion of this subject Tuffer advises gastroenterostomy before perforation has taken place in those cases in which a diagnosis can be established.

TWO CASES OF RESECTION OF THE LARGE INTESTINE, WITH RECOVERY.

Ev'r's first case (Medical Press and Circular, May 17, 1899) suffered from a large left scrotal hernia, strangulated for three days. Herniotomy showed that the sac contained a knuckle of the transverse colon, which was gangrenous. A glass tube was inserted into the intestine, and the latter was attached to the wound. Five weeks later the intestine forming the artificial anus was brought out of the abdomen after opening the peritoneum, and was resected and sutured. The intestine was returned, and the abdomen closed. Primary union and recovery without complication.

The second case was an example of carcinoma of the descending colon. A woman, aged forty-seven, had suffered with pain in the abdomen, vomiting, and constipation for seven months. A tumor in the left loin, just below the ribs, had been noticed for some months; it was movable from side to side, and evidently situated in the descending colon. The constipation culminated in an attack of obstruction, during which the first operation was performed. This consisted in bringing out the tumor with several inches of healthy bowel, and fixing the bowel to the parietes. The bowel was drained by the insertion of a glass tube. Ten days later the protruding portion of the bowel was removed, and the mesenteric edges of the divided ends were brought together with sutures. After allowing an interval of a month for the inflammatory effusion around the wound to become absorbed, an incision was made around the artificial anus down to the peritoneum. The latter was not opened, but was separated from the parietes for about two inches all round the protruding bowel. The free ends of the intestines were refreshed and brought together with Lembert sutures. The parietes were then closed over the bowel. The wound was completely healed three weeks after the operation. At the present time the patient appears perfectly well, and has suffered no inconvenience.

The writer is of opinion that in these and similar cases the bowel should be drained, even although only moderate symptoms of obstruction existed.

Although Murphy's button could be inserted very rapidly and readily, the intestines could not be completely drained, and in this case the shock of the resection was added to the illness from which the patient was suffering.

The author thinks that for the large intestine, at any rate, suture is safer than the use of Murphy's button.

The second case was published especially to draw attention to the merits of extraperitoneal resection and suture for artificial anus.
as the safest method. It was introduced by the late Dr. Greig Smith. This operation was attempted in the first case, but had to be abandoned owing to the extreme thinness and friability of the peritoneum. This was probably due to stretching of the membrane from the presence of a large hernial sac in its neighborhood.

CURE OF ASCITES DUE TO LIVER CIRRHOSIS BY OPERATION.

MORISON (The Lancet, May 27, 1899) reports a case of ascites due to liver cirrhosis successfully treated by operation, and further records the post-mortem findings in a woman operated on two years ago. These showed clearly the free vascularity of the adhesions which united the liver, spleen, intestines, omentum, and parietal peritoneum. This specimen establishes our belief that an efficient anastomotic circulation can be brought about by operation. There can also be no doubt that this patient was cured of ascites, and that useful life was prolonged to her for two years by the operation. A further examination of the specimen showed the liver to be much atrophied and degenerated. The spleen was at least four times its normal size. It is quite evident that the obstructed portal circulation had nothing to do with the splenic enlargement—in this case at all events—for the new anastomotic circulation was clearly more than sufficient to compensate for any diminution in size of the portal vein.

The author states that it is more rare than he thought to see uncomplicated cases of liver cirrhosis and ascites. Valvular heart lesions, thoracic aneurism, albuminuria, and glycosuria are the most frequent complications which he has met with, and each would seem to contraindicate operation, because but seldom can the latter be but temporary. Of the two previously recorded cases one was successful in curing the ascites, the other was not. The clinical diagnosis of liver cirrhosis was not in the latter case corroborated by surgical examination of the liver, and Dr. William Ewart suggested at a meeting of the Harveian Society of London on April 6, 1899, that this case might be similar to one under his care. In his case the operation failed to cure an obstinate ascites which was believed to be due to liver cirrhosis, and his patient died, like the author's, several months after the operation. In his case the post-mortem examination showed a universally adherent pericardium, stiffened by a layer of calcareous salts which must have precluded the contraction of the ventricles. The liver was not cirrhoried.

The author has now operated on four cases. Two were uncomplicated and were regarded as suitable cases for operation, and both of them were cured. In one the diagnosis was doubtful, and in another the complications were such as to preclude recovery.

The conclusions which the author has come to are as follows:

1. Ascites due to liver cirrhosis can be cured by the establishment of an efficient anastomotic circulation.

2. Adhesive peritonitis produces adhesions between the abdominal contents and its parietes, in which new blood-vessels form. If there is any demand for the new blood-vessels they remain permanently.

3. The operation described in the paper by Drummond and himself (British Medical Journal, Sept. 19, 1896) is the safest and most certain method of producing adhesions.

4. It is no longer advisable to treat the ascites due to cirrhosis by repeated tappings if the patient is otherwise sound and in fair general condition. After one or two tappings have failed operation offers the best chance of a prolonged and useful life.

A SERIES OF CASES OF ARTHROTOMY FOR THE RELIEF OF PAIN, REMOVAL OF SYNOVIAL FRINGES, LOOSE BODIES, AND FIBROCARTILAGES.

LOCKWOOD (Medical Press and Circular, May 17, 1899) first referred to four cases in which the wrist-joint had been opened for the relief of pain. Two of these occurred in women, and were possibly pyemic. The joints were opened by longitudinal incision between the extensor tendons, and were drained for some days, after which the wound completely healed. The relief from pain was immediate and permanent. The third case occurred in a man, and was proved by histological examination to be tuberculous. It was treated in a manner similar to the two former cases. Pain was immediately and permanently relieved, and the disease was arrested. The fourth case also occurred in a woman. The inferior radioulnar articulation was inflamed, and had been for four years, and was the seat of extreme pain. It was opened by dorsal incision, and as the cartilage covering of
the lower end of the ulna was eroded and
the bone inflamed, the head was removed.
The incision was closed without drainage,
pain ceased, and the ultimate recovery was
perfect.

It was pointed out that in all these cases
the operation was performed for the relief of
pain. Mr. Lockwood had often performed
arthrotomy in cases of acute septic arthritis
in which pain had been present. Obviously,
under these circumstances, the operation was
not performed for the relief of pain, but to
give exit to septic or purulent fluid.

Arthrotomy for the removal of inflamed
and elongated synovial fringes was next re-
ferred to. The case of a married woman
was described at length. For six years she
had had repeated attacks of synovitis; lat-
terly the swelling and inflammation of the
knee-joint had become almost continual.
The symptoms were very like those which
are caused by the presence of a loose body
within the joint. None could be detected,
and the joint was opened. The absence of a
loose body was confirmed, but the whole of
the synovial fringes of the joint were observed
to be exceedingly long and inflamed. It
seemed likely that some of them might have
been nipped betwixt the articular surfaces.
They were all removed. For this purpose
the ligamentum patellae was divided. A
speedy recovery ensued. Nine months after
the operation she said that the knee was bet-
ter than it had been for years; she was able
to walk about and perform her household
duties. The movements of the joint were
good and painless; it contained no fluid.
Mr. Lockwood thought the membrane was
still a little swollen. In connection with this
case, the best manner of opening the knee-
joint for the total removal of fringes was dis-
cussed. Another case of a similar character
was likewise described.

Next some cases of arthrotomy in chronic
osteoarthritis were described. These were
undertaken because the chondrical and ossi-
sified synovial fringes got betwixt the articular
surfaces, either by having become detached
or because of very long pedicles. One of
these patients was in her seventieth year.
Nevertheless, three weeks after four loose
bodies had been removed from the joint
she was walking about. In a second case,
in addition to pedunculated cartilaginous
fringes, a pedunculated fatty growth of the
synovial membrane was taken away. In yet
another case of osteoarthritis a pedunculated
fringe was removed. The joint ceased to
lock, but the operation was followed by a
certain degree of stiffness due to the progress
of the osteoarthritis. The avoidance of this
complication was discussed.

Finally cases of excision of the internal
semilunar fibrocartilage were mentioned.
One was described in which the history four
years after the operation showed that the
result had been perfect. In a second case
of removal of the internal semilunar fibro-
cartilage the history was brought down to
three years after the operation. With the
exception of the scar the knee-joint was nor-
mal. The patient led a most active life and
considered the joint as good as the other,
quite perfect in spite of the absence of the
fibrocartilage. The third case was peculiar,
having occurred in a woman. In this, again,
the removal of the fibrocartilage, whilst curing
the locking of the joint, was attended with
no other appreciable effect.

SENIILE ENDOMETRITIS.

J. Lorain (La Revue Médicale; quoted in
Annals of Gynecology and Pediatry, May, 1899)
says that one of the first symptoms of senile
endometritis is a semipurulent yellow or
greenish discharge, often streaked with
blood, and occasionally offensive; the dis-
charge is sometimes continuous, sometimes
intermittent. Metrorrhagia is not rare, and
is occasionally so marked as to give rise to
what is described as the hemorrhagic form
of the disease; the loss of blood is, however,
rarely great, and never by itself constitutes a
great symptom.

The disease is usually but slightly painful,
the subjective symptoms being limited to a
feeling of weight in the hypogastrum and to
sacroalgia. Sometimes, however, the patient
complains of smaring and itching about the
vulva; in most cases this is due to the irrita-
tion of the discharge, but occasionally no
signs of inflammation are present. Fre-
quency of micturation and pain after the act
are sometimes observed.

There is little tendency for the inflamma-
tion to spread to the Fallopian tubes, but
this does occasionally take place. Perime-
tritis and parametritis are practically never
found.

The uterus is usually found to be of normal
size, mobile, but slightly tender; the specu-
lum reveals a cervix more or less inflamed,
of a deep red color, swollen and smooth.
Cervical erosion is rare.
The course of the disease is essentially a chronic one; the symptoms become more marked after exertion and fatigue; but the acute or subacute exacerbations found in endometritis anterior to the menopause, and probably due to menstrual congestion, are not found in senile endometritis.

The general condition of the patient is always to some extent affected by the disease; loss of flesh, anemia, dyspeptic troubles, occasionally rigors and night sweats, and, in fact, a condition of cachexia more or less marked, are found.

The diagnosis of senile endometritis is of the greatest importance, owing to the resemblance its symptoms bear to those of cancer of the body of the uterus. The treatment depends essentially on an accurate differential diagnosis. If the disease is merely endometritis, medical treatment will always guarantee a cure. On the other hand, if the disease is cancer of the body, hysterectomy, at least in the early stages, is the only rational treatment, and the prognosis becomes grave, not only by reason of the dangers of the operation itself, but also because of the grave risk of a recurrence of the disease.

Treatment should have two ends in view: (1) To allow of the free escape of the secretions of the uterine mucous membrane; (2) the application of antiseptics to the interior of the uterus.

The free escape of the contents of the uterus is of special importance, since, as long as these are pent up in its cavity, no cure can be expected. Generally speaking, the dilatation of the cervical canal is best effected by Hegar’s dilators; but cases arise in which the stenosis of the cervical canal is so advanced that the smallest dilator cannot be introduced; in such cases dilatation must be obtained with laminaria tents. It is generally sufficient when the passage of Hegar’s No. 7 or 8 can be effected, but this will often require two or three sittings at intervals of twenty-four or forty-eight hours. After dilatation, one of the following solutions should be applied to the cavity of the uterus:

Creosote,
Glycerin,
Alcohol, equal parts of each.

Or,
Ichthyol, 10 parts;
Glycerin, 40 parts.

Or pure tincture of iodine should be applied.

These are introduced into the uterus by means of a flexible sound, the last two inches of which is surrounded by cotton-wool; this is then soaked in the solution and applied to the whole surface of the uterine mucous membrane. The treatment should be renewed two or three times a week, and in the intervals a drain of antiseptic gauze should be left in the uterus, a tampon of similar gauze being left in the vagina.

As the cervical canal tends to contract up again between the dressings, it will be found necessary to further dilate it from time to time.

The duration of treatment carried out according to the above principles will be found to be approximately from three to four weeks.

OPERATIVE TREATMENT OF GLANDULAR HYPOSPADIAS.

VON HACKER (Beiträge zur Klinischen Chirurgie, Band xxii, Heft 1; quoted in Annals of Surgery, June, 1899) recommends an operation differing considerably from the ordinary methods. The urethral orifice, together with its corpus spongiosum, is freed from its surroundings, the dissection being carried well backward. The glans is tunneled through, the urethra is pulled forward, and the meatus is sewn to the external surface. The advantages claimed for the operation are:

1. It does away with the necessity of operating in several sittings.
2. It insures greater certainty of union, other methods frequently requiring repetition of the operation and secondary measures for closure of fistulae.
3. As there is an absence of any canal requiring to be covered over, a catheter d demure is unnecessary. No subsequent constriction of the opening is to be apprehended.
4. The urethra remains surrounded by its corpus cavernosum, and the new external orifice by erectile tissue in a nearly normal fashion—the latter circumstance being highly desirable for the proper ejaculation of semen.

Reviews.

The announcement that Dr. Cushny was about to publish a book on Pharmacology was hailed with interest by the American
medical profession, because those who are interested in scientific therapeutics recognize the fact that his training and experience well qualify him for the preparation of such a manual. The book has appeared, and we have given it an exhaustive and thorough examination; after doing this we wish to give it the highest praise which is in our power, and to express our sense of obligation to Dr. Cushny for having prepared so competent a volume.

After saying this, and with no intention of modifying it by what we may say further on, we shall consider ourselves at liberty to differ from the author in certain statements which are made.

The opening pages of the book, dealing with the general consideration of the subject of pharmacology and therapeutics, are admirable, although we are somewhat disappointed that under the section devoted to the chemical character of drugs more is not said about the relation of chemical constitution and physiological action. Of course, this subject is as yet almost an untilled field, and yet it is a very important one. We are interested to note the classification of drugs which has been made by this author, and while it is a classification instituted by older and more experienced pharmacologists, and somewhat modified by him, we think that like all other classifications which we have seen it is open to many objections. As an illustration of the fact that this classification is difficult, we find that the nitrites are classed under the heading of "organic substances characterized chiefly by their action after absorption." Surely the nitrites can hardly be called organic substances in the ordinary sense of the term, nor can formaldehyde, benzol, and similar substances come under this heading by any consideration except that of utility. We believe that the author recognizes this fact as well as we do.

The remarks made by Dr. Cushny in regard to the methods by which pharmacology and therapeutics should be taught seem to us singularly appropriate at this time.

It strikes us as somewhat odd that many of the drugs are classed under the names of their active principles rather than under the name of the crude drug; thus we cannot see why lobelia should be considered under the heading of lobeline, or tobacco under nicotine, or veratrum viride under veratrine. Surely the physiological action and therapeutic uses of veratrum viride in the form of a tincture or fluid extract are not in any way similar to those of veratrine, and many physicians who are in the habit of considering veratrum viride a valuable drug will not be satisfied with finding but two and a half lines devoted to its uses, nor believe in the statement that as the activity of veratrum viride is due to veratrine it may well be discarded from the Pharmacopoeia. This statement is so utterly antagonistic to the opinion of many reputable practitioners that it does not require further criticism and may be considered as distinctly erroneous.

We do not think that under the consideration of antipyretic drugs sufficient emphasis is laid upon the fact that these drugs diminish the production of heat as well as increase the dissipation of it, neither do we agree with the author when he states that there seems to be no reason why the combination of the two methods—that is, cold bathing and coal-tar products internally—should not prove more efficacious than either alone. In this instance such a combination is distinctly deleterious in its influence. The great objection to all the coal-tar products in practice is that they destroy the patient's reaction. The greatest advantage in cold-bath treatment in all its forms is that it improves the patient's reaction, and the use of the coal-tar products simultaneously with the cold bath exposes the patient to internal congestions and deprives him of the physiological process by which he would not only resist the effects of cold but obtain advantage from it.

We also differ from the author very distinctly in the statement that in therapeutics digitalis never causes irregularity of the heart. Those who have had experience with digitalis when given in full doses and continued to the point of irritability very frequently find that it produces marked cardiac irregularity. Again, we do not think that the statement that digitalis does not influence the heart favorably through its effect on the pneumogastric nerve is correct, and the comparative statement that aconite, which stimulates the pneumogastric, does not improve the heart is not a fair comparison.

Finally, the statement that the action of digitalis is the same as ergot in stopping hemorrhages from small vessels may be correct, but neither of them is of any practical value, we believe, for this purpose.

In the consideration of saline cathartics nothing is said of their use in the treatment of peritonitis, which we think is an unfortunate omission, but we heartily agree with the
author in his statement that the hypophosphites are not the remedies which they are "cracked up" to be. We have long believed the usefulness of the hypophosphites in the treatment of disease is greatly exaggerated.

What Dr. Cusnny has to say about the value of lithium for uric acid is not only of interest but exceedingly valuable, and it is evident that the lithia salts are by no means as useful in this condition as some persons would have us believe; in this we entirely agree with him.

Dr. Cusnny states that lime salts are not likely to be of benefit in rickets unless it is due to lime starvation, a condition which is not likely to arise in a human being. In the treatment of phosphorus poisoning we regret to see he recommends the employment of turpentine oil, which in its ordinary employment we believe to be valueless. We do not think he emphasizes the value of permanganate of potassium sufficiently.

Credit is given for the introduction of calomel in the treatment of dropsy to Jendrassik, when it really ought to be given to Dr. John Kearsley Mitchell, father of Dr. S. Weir Mitchell, who as professor of practice in the Jefferson Medical College taught this use of calomel before Jendrassik was a practitioner of medicine.

While the bibliographical references which are appended to most of the articles show that the author has a wide knowledge of European pharmacological literature, and while it is true that American and English pharmacological literature is comparatively scanty, we regret that so few references to English and American researches are made. Surely some of them have been of sufficient value to have some influence upon the statements made in his book; but we can readily understand that as Dr. Cusnny received his pharmacological training chiefly in a German university his acquaintance with German literature overshadows his acquaintance with that in other languages.

After these criticisms, which are criticisms of detail rather than of the whole book, there is nothing left but to reiterate the words of praise with which we began this review.

A sufficient amount of therapeutic information is not to be found in the volume to make it useful to the practitioner; and as we understand it Dr. Cusnny did not intend to prepare a work on therapeutics, but did intend to prepare one upon pharmacology, and in this respect he has attained a noteworthy success.

Materia Medica, Therapeutics, Medical Pharmacy, Prescription Writing, and Medical Latin. A Manual for Students and Practitioners. By William Schleiff, Ph.G., M.D.

The book before us is a small octavo volume of about 350 pages, in which the drugs are classified in a manner closely resembling the classification of drugs adopted by H. C. Wood in his well known "Therapeutics;" indeed, in some respects it may be considered a condensed manual of that work. As is seen from the title, the author has made its pages cover a very wide field, but when one reads the book it is discovered that it deals with drugs chiefly, and to a very slight extent with prescription writing and medical Latin. Naturally the book follows very closely the teachings of Dr. Schleiff's superior, Dr. H. C. Wood, and will doubtless prove popular with the students of the University of Pennsylvania and others, who will find in it much of the information which they desire.

The present volume is the twenty-seventh annual report of the Marine Hospital Service, and this is the one hundredth year of the existence of that service. The report is of unusual interest because it embodies a period in which our relationship with neighboring countries, in which a number of contagious diseases are endemic, has become more than ever intimate. Each year shows an increased activity in scientific effort among the members of this very valuable branch of the Government, and Dr. Wyman, the Surgeon-General, is to be congratulated upon the high standard and efficiency which the service has attained under his executive control.

This is one of Blakiston's well known quiz compends, and is written not in the form of questions and answers, but in the manner in which a small manual is usually composed. It is needless to say that the authors, who are careful workers in everything which they undertake, have taken pains to make accurate every statement in its pages, and while it does not in any way attempt to present original characteristics, it is a first-rate brief guide to ophthalmic practice.
Correspondence.

London Letter.

By Raymond Crawford, M.A., M.D. Oxon., M.R.C.P.

Dr. Short's paper to the Midland Medical Society on the "Treatment of Occupation Neuroses" is worthy of attention for his very common-sense treatment of these much abused disorders. His remarks on writer’s cramp are particularly to the point. It is idle to enjoin complete rest to a class of patients for whom such an impossibility for pecuniary reasons, and complete rest is only essential in the early stages, when pain is present. Such pain is best relieved by the local application of belladonna, and rest. After the relief of pain, the most important point is to keep up the nutrition of the muscles by passive movements and electrization, at the same time encouraging in the patient a confident hope of recovery, as in most of these cases a powerful mental influence is at work. Active muscular exercise of some kind should be insisted on, such as carpentering, or knitting, so as to maintain the power of the hand muscles, while at the same time giving relief from the actual work of writing. Care, too, must be bestowed on the actual mode of writing; this will usually be found to be cramped and throwing all the work on the small muscles of the hand. Writing from the shoulder should be studiously cultivated, and this can be best effected by writing large letters on a blackboard or on a sheet of paper on the wall; the position of writing necessitates then the use of the shoulder muscles. Twenty minutes of this exercise twice a day is sufficient at first. With these precautions carefully obeyed, some amount of writing may usually be permitted to the sufferer in his daily occupation. Here, too, much can be done by attention to details. The table should not be too high for the chair, or undue pressure will be exerted on the ulnar border of the forearm and irritate the ulnar nerve. A thick penholder is better grasped than a thin one, and it should not be unduly light, as this diminishes its momentum in writing. Ball-pointed or quill pens are the best, but a quill pen is too thin for an easy grip. The study of shorthand is a very excellent training of the muscles of the hand, and may be of commercial value to the patient. It is a first-rate training of delicate movements, and it is a familiar fact that shorthand writers are singularly exempt from writer's cramp. Text-books dismiss the treatment of this distressing ailment with the magic word "Typewriter," but in the practical work of the office type and manuscript are seldom interchangeable. Over and above this, all such measures are indicated as promote well-being of mind and body.

The annual meeting of the British Medical Association at Portsmouth has come and gone. It has been voted on all hands a success, not perhaps in the sense that the Association might have wished, however. Statistics are sometimes misleading, but when I tell you that out of 900 members present at Portsmouth, only twenty-five were present at some of the sectional meetings, while the remaining 875 dispersed themselves on the waters of the Solent, you will agree with me that as a nation we no longer "take our pleasures sadly;" albeit the Association was established "for the promotion of medical and the allied sciences, and the maintenance of the honor and the interests of the medical profession." On the whole the interest of the meeting centered on the prevention and treatment of tuberculosis—a time-honored theme that in England has only recently been admitted within the pale of practical therapeutics. There was a great deal of interesting material in the Section of Pharmacology and Therapeutics, presided over by Professer Bradbury. Dr. Lauder Brunton dealt in his charmingly transcendental manner with headaches and their treatment. Migraine he ascribed to toxins circulating in the blood; in health these toxins were
rendered innocuous by the activity of the liver. We fancied that Dr. Brunton suggested that the reason why the head was most often affected was that commonly this was the seat of lowest physiological resistance. This is decidedly an unpleasant reflection, though Dr. Brunton specifies such minor and non-psychical defects as curious teeth and errors of refraction. The necessity of a major premise to give verisimilitude to his conclusion induced Dr. Brunton to assert that there was a form of "headache" which occurred in the abdomen, due likewise to general toxemia. In treatment, and therein we bow the knee to Professor Brunton, he urges the use of cholagogues, and more particularly of salicylate of soda—preferably in combination with bromides. Whatever is taken must be taken before the headache is fully established, as absorption by the stomach is then at a standstill, and no drug given by the mouth will produce any effect.

Dr. Burney Yeo followed with a very practical paper on "Intestinal Antiseptics." He cited Dieulafoy's experiments upon the bacillus coli as the scientific basis for their employment. Dieulafoy showed that the virulence of this organism was markedly enhanced by a suitable environment; in fact, the organism may be regarded as innocuous in the normal conditions of health. Logically, then, changes of environment, such as may be effected by antisepsis, should serve to modify the virulence. Incidentally Dr. Yeo alluded to the value of antifermentatives in the treatment of many disorders of digestion, and the value of intestinal irrigation of the bowel with sterilized water in cases of summer diarrhea. In this country Dr. Yeo is rightly regarded as the pioneer of the antiseptic treatment of typhoid fever, and those who have seen his results with chlorine water and quinine will certainly be loath to relinquish this method. Dr. Yeo has always maintained that the use of chlorine water as a routine method in all cases of typhoid fever is absolutely unscientific, and very harmful. The virulence of certain cases of typhoid fever appears to depend on the associated activity of other putrefactive organisms; on the virulence of these chlorine water has a very marked effect, deodorizing the excreta and lowering the septic fever in a marked degree. In mild cases, where the fever is low, no conceivable advantage can be derived from chlorine, which has no controlling influence over the activity of the typhoid organisms; moreover, the chlorine mixture is apt to irritate the stomach and interfere with its function, just when its activity is needed unimpaired. In certain indefinite febrile affections pointing to intestinal disorder, Dr. Yeo advocated the employment of thymol by the mouth, and irrigation of the large bowel with eucalyptol, olive oil, and soap and water. In the early stages of typhoid fever Dr. Yeo recommended the use of calomel and salines. Salicylate of bismuth and carbolic acid were both of use in appropriate cases. Salol he had found disappointing, or rather uncertain in its action.

Dr. Hugh Walsham made a communication on some cases treated with erythrol tetranitrate. This drug, it will be remembered, was introduced to the public a few years ago by Dr. Bradbury, the President of the Therapeutic Section. In some cases it is certainly more effective than nitroglycerin, but it has scarcely received the attention it deserves from some quite unfounded fear of its explosive properties, based on its abuse in one or two instances. Dr. Walsham pointed out that this danger could be absolutely forestalled by giving the drug in chocolate tablets. He had found it of use in angina, in Raynaud's disease, and in the sleeplessness of chronic interstitial nephritis. Professor Bradbury confirmed these observations and mentioned incidentally that he had given a patient as much as one drachm twice a day.

The papers by Dr. Schiff, of Vienna, on "The Use of the X-rays in the Treatment of Skin Diseases," and by Dr. Hall Edwards, of Birmingham, on the "Therapeutic Effects of X-rays on Lupus," were both of very great interest. As long ago as 1896 Dr. Freund, of Vienna, used X-rays successfully in the treatment of hypertrichosis, and this had encouraged Dr. Schiff to test its efficacy in lupus and other skin diseases, as the active agent of the X-rays, whatever it may be, undoubtedly penetrates to the deeper layers of the skin; by graduating the strength of the X-rays the resulting inflammation could be increased or diminished at will. Dr. Hall Edwards regarded the resulting dermatitis as of the nature of an electrostatic burn. The inflammation appeared to cause the root of the hair to separate from the bulb, while the changes set up in the tissues resulted in the conversion of chronic granulations into normal connective and scar tissue. There can be little question from experiments with the X-rays on bacteria that the effect is not bacicidal in character. Dr. Schiff urged on these grounds the efficacy of the X-rays.
(1) in affections in which the removal of hair for as long as possible was advisable—herpeticosis, trichorrhexis, sycosis, favus, and herpes tonsurans; (2) in cases where a change of the tissues in the lower layers was necessary—acne follicularis, acne rosacea, lupus vulgaris, lupus erythematoses, eczema chronicum, elephantiasis Arabum, and oedema chronicum. Dr. Hall Edwards's paper related to the good results he had found in the treatment of lupus, and these were strikingly attested by the photographs of actual cases.

In the Section of Surgery Mr. Berry's communication on "Seventy-two Consecutive Cases of Goitre Treated by Operation" was received with favor, as from one who has had a very wide experience of these cases. In thirty-three of the cases one lobe of the gland with its capsule had been extirpated, and in thirty-nine adenomata had been enucleated from the thyroid. Mr. Berry at the outset emphasized the fact that many cases of goitre are curable by simple medicinal measures, and this knowledge should give pause to a hasty recourse to operation; and furthermore, the operation should only be performed under exceptional circumstances for mere deformity. Dyspnea was by far the most common plea for interference, and dyspnea tended to occur in two main classes of cases: first, in rapidly growing parenchymatous goitres, in which extirpation is necessary; and secondly, for goitres where the enlargement was low down behind the sternum. Mr. Berry was of opinion that where there is no dyspnea a general anesthetic may be given, but that when dyspnea is present a local anesthetic should be employed. I can confirm Mr. Berry's commendation of the local anesthetic, having more than once seen his operations under a local anesthetic. Mr. Berry declared in favor of the single oblique incision, though the transverse incision leaves a less noticeable scar, because of the greater ease of operation. It is desirable to divide the infrahyoid muscles, not immediately underneath the skin incision, as this endangers adhesion of the cicatrix; it is well also to suture the divided infrahyoid muscles.

In the Section of Ophthalmology Dr. Hinshelwood, of Glasgow, read a paper on "The Use of Euphthalmine as a Mydriatic." Two or three drops of a five-per-cent solution produced dilatation of three hours' duration in twenty minutes, and the effect can be even more rapidly produced by previously instilling a single drop of a one-per-cent solution of holocaine. Euphthalmine has the advantage of being much cheaper than homatropine. Mydrine resembles euphthalmine in action, but is a very expensive drug.

Reports received from Sierra Leone from the expedition sent out by the Liverpool School of Tropical Medicine state that Major Ross has succeeded in proving, as he had surmised, that the malarial organism is propagated by a particular species of mosquito. So far he has succeeded in demonstrating the presence of the organism in situ, and has located the haunts of large colonies of the offending mosquito. The next step appears to be to see how far sanitary measures can serve to stamp out the existence of the offender.

The chair of physiology in University College, London, has now been filled by the appointment of Dr. Starling, a young candidate, but one who has already done much original research work.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

In a recent number of the Presse Médicale a treatment of cholera infantum, based on the works of Baginski, Hutinel, Marfan, Sevestre, Thiercelin, and Lesage, is given at length. The author of this article, Dr. Pliche, began by saying that the treatment of this affection is very urgent, and as much so as in a case of appendicitis. Infection, and consequently intestinal poisoning, are the principal factors of what is called summer disease. There exist two distinct varieties of this affection—the febrile form, accompanied by fever, typanites, a red, dry tongue, which has been studied by Dr. Sevestre, physician of the children's hospital; and the algid form, due in some cases to the preceding one, and ending fatally in a great many cases.

The most important part of the treatment is the diet to be followed. No milk should be given for twenty-four or forty-eight hours, and as the thirst is considerable, water either boiled or sterilized should be given in sufficient quantity. A good mixture is very weak tea with a little iced champagne. Black coffee in small quantities is also useful. Malaga wine with boiled water, and very weak grog prepared with tea, are also useful. Drs. Despine and Picot, of Geneva, have given as much as thirty to sixty grammes of cognac in tea or boiled water. When the condition
is not serious, chicken broth is a good preparation; albuminous water is not so useful as has been thought, as it may ferment. Rice-or barley-water is an excellent preparation, but is often badly prepared. Dr. Marfan has given a good recipe: two teaspoonfuls of barley should be boiled in half a liter of water, then passed through a cloth. About a liter to a liter and a half of liquids should be given daily. About the only drug which has seemed to have any effect is lactic acid. Hayem and Lesage recommend giving every half-hour a teaspoonful of the following solution:

Lactic acid, 3 grammes;
Quince syrup, 5 grammes;
Distilled water, 100 grammes.

The solution should be iced, and after each spoonful some water should be given. After three hours the lactic acid solution should be given only every hour. This preparation should be withdrawn as soon as milk is given again. Intestinal antiseptics are useless; calomel is sometimes useful in fractional doses of one centigramme every three hours. Opium has its defenders, and Despine and Picot consider it as their reserve drug. They give the following solution:

Paregoric,
Lactose,
Spirits of melissa, 1.5 grammes;
Lactic acid, 1 gramme;
Infusion of tea, 100 grammes.

Teaspoonful every two hours until an effect is produced.

Lesage, who has written the article on this affection in the Treatise on Children’s Diseases, edited by Comby and Marfan, recommends applying a wet compress on the abdomen. Baths at a temperature of 38° are often useful, but the temperature, according to Lesage, should vary with that of the patient, warm baths being given when there is hypothermia, and cold in the contrary case. Washing out of the stomach and the intestines is a useful method in hospital practice, and an effort should be made to use it in ordinary clientele. Hypodermoclysis with Hayem’s or the normal saline solution produces a most excellent result in some cases. From 150 to 300 grammes may be injected daily in five or six injections. Injections of caffeine are also sometimes of benefit.

At a recent meeting of the Society of Neurology Drs. Marechal and Glorieux gave their results in the treatment of sciatica by copaiba. The usual dose is eight to ten capsules. Dr. Crocq has also published recently in the Journal of Neurology an essay on the treatment of sciatica, and wrote favorably concerning ichthyol. In twenty cases of sciatica, fourteen were cured, and there were four cases in which a noted improvement was observed. There were two failures. The mode of administration consists in giving six to eight capsules daily containing ten centigrammes, and using a liniment made with the following formula:

Ichthyol, 50 grammes;
Glycerin, 20 grammes;
Water, 30 grammes.

Certain cases dating from a year were completely cured in this way.

The Dreyfus trial at Rennes, which is exciting so much attention on both sides of the Atlantic, has had its medical aspect too. My readers have already heard of the dastardly attempt that was made on Labori by some miscreant who has not as yet been discovered. By the best of chances there happened to be at Rennes Dr. Reclus, one of the most celebrated Paris surgeons, and Dr. Brissaud, a well known neurologist. It was found on examining the patient with the Roentgen rays that the ball after having pierced the muscles of the vertebral region had flattened itself against the transverse process of the fourth vertebra. Dr. Doyen, who has acquired a world-wide reputation, thanks to his efforts, packed up his instruments and took the train for Rennes as soon as he heard of the accident to his good friend Labori. On the plea of his being a friend, and notwithstanding the fact that he had not been called by the family, he endeavored to inquire into the condition of the patient more than Dr. Reclus thought was discreet. There was a somewhat acrimonious dispute, and Dr. Doyen’s case was published in the Figaro in an article where the old methods of leaving a projectile were criticized and Dr. Reclus placed in an awkward position. Thereupon the family of Labori published a few lines in which they showed that Dr. Doyen had not been called in, and that Dr. Reclus inspired them with perfect confidence.

At the recent gynecological congress held at Amsterdam, a few words of Dr. Doyen’s were taken up in a way which showed that he is not looked upon favorably by the Paris school of surgeons. There is always a certain rivalry between the surgeons of the Paris hospitals and the provincial surgeons, and Dr. Doyen, who left Reims recently to establish himself in Paris, has carried the battle into the enemy’s camp.

Therapeutic Gazette.

*Original Communications.*

ON THE CHOICE OF OPERATION FOR STONE.

By John H. Brinton, M.D.,
Professor of the Practice of Surgery and Clinical Surgery in the Jefferson Medical College of Philadelphia.

(Continued from page 673.)

SUPRAPUBIC CYSTOTOMY.

Of all modern operations, scarcely one has grown more rapidly into favor than this form of cystotomy. Although an old procedure, and one long since regarded as dead and laid to rest, it has of late years been fully resuscitated and so modified that it ranks as one of the most trustworthy efforts of modern surgery. As now practiced, and with the saving precaution of antisepsis, the old-time peril of peritonitis, so dreaded and so fatal, has been practically done away with.

Familiar as this operation is, it may perhaps be permissible to say a few words of the suprapubic, or high, cystotomy as we now do it.

Before operation, the patient should be placed in a modified Trendelenburg position, with his hips and pelvis raised. The dependency of the intestinal coils is thus favored, with a corresponding retraction of the upper vesical fold of peritoneum. A degree of im-
munity against wounding the peritoneum is thus afforded.

The bladder is then well distended with water—by some surgeons air is preferred; an india-rubber bag should then be inserted into the rectum, which when filled with ten or twelve ounces of water will lift the summit of the bladder upward and forward above the pubis; here it is entirely accessible to surgical manipulation. This injection should be made gently, so as to avoid rupture of the rectum, an accident which has occurred. A longitudinal incision two and a half inches long should be made through the integument over the lower fourth or fifth of the linea alba, and carried well down on the pubis so that the top of that bone may be readily felt. The incision is then deepened between the muscular structures upon either side until the vesical fat above and behind the pubis is reached. This should then be divided and separated in the median line until the front of the bladder is exposed, care being taken not to wound the numerous deep veins on either side. If these be cut or torn, such bleeding may occur as to prevent the recognition of tissues, and retard the operation. The superior vesical fold of the peritoneum must now be carefully looked for, and if seen, it must be carefully retracted upward. Should it be accidentally wounded, the cut must be at once stitched up, before any opening is made into the bladder.

The front surface of the bladder, when reached, may be readily recognized by its pinkish color, and by its rotundity of distention under digital palpation. A tenaculum should then be inserted through its walls, the operator being sure that the peritoneal fold is out of the way and intact. The handle of the tenaculum should then be given to an assistant, who with it draws the bladder to the upper angle of the wound. An incision is then to be made well upon the anterior and upper convex surface of the bladder. This opening should be high up, so that if fistula should ultimately follow, the level of the contained urine may be at the highest line. This would give the greatest permanent capacity of the bladder, and will greatly contribute to the comfort of the patient in after-life.

The incision should be from three-quarters of an inch to one inch in length, sufficiently large to permit the introduction of the forefinger and the exploration of the bladder. If the calculus be large, the incision may be extended to any necessary length. The hold of the transfixing tenaculum should be always preserved, so as to prevent the falling back and collapse of the bladder, and premature escape of its contents, a source of hindrance to further exploration. By some surgeons a looped ligature passed through the bladder wall by a curved needle is preferred to the tenaculum.

If any stone be found, it should be removed by the forceps. The bladder should then be washed out by the antiseptic douche, and thoroughly explored. In many instances, where it is advisable, the examination of the bladder may be assisted and made exhaustive by the use of reflected or electric light.

After operation urinary infiltration may be prevented by inserting through the wound a rubber drainage-tube of a quarter of an inch caliber. This may be rounded at the vesical end, and fenestrated, and may be stitched to the edges of the integumental wound. It should be long enough to empty by its external end into a receiver. If at any time it should become choked, the obstruction may easily be removed by injection of air or water, from a rubber bulb or small syringe.

The retention of this drainage-tube need not be prolonged; it can usually be taken away at the end of two or three days, and the escaping urine may be received on pads of gauze, which should be changed every four or five hours. The position of the patient in bed may be at his pleasure—recumbency either on his back or side. This may be left entirely to his own wishes. The old idea was that to prevent infiltration he should be kept strictly on his back, especially after the drainage-tube had been taken away. This I disregard, and I have never observed any evil consequences to follow the assumption by the patient of the attitude in bed which is most comfortable to him. On the contrary, when he rests at will, he experiences less bladder irritation, sleeps more readily and uninterruptedly, and his convalescence is in every way more speedy and satisfactory.

The healing of the external wound usually takes place rapidly, by granulation on its sides. The incision in the bladder gradually contracts, and about the tenth or twelfth day, and sometimes earlier, the urine begins to flow through the urethra. By some surgeons a soft catheter is inserted into the bladder, immediately or early after the operation, but this usually is not necessary, as the drainage through the wound takes care of itself, and the patient is much more comfortable if spared the annoyance of a retained
catheter, ever an obnoxious foreign body, and especially so after vesical operation. Occasionally the closure of the wound of operation is tardy, a fistula is threatened, and the patient becomes much disturbed in mind at the very idea of an open urinary track. It is then the duty of the surgeon to allay the patient’s apprehensions and to calm his mind. My experience of such cases is that generally the fistula eventually heals. Even should it remain open for some time, the occurrence is not to be deprecated, for the bladder is as it were under tolerant examination all this time.

Should any tendency to fresh stone formation exist, and this is not uncommon in old bladders with enlarged prostate and phosphatic urine, the presence of these new calculi can certainly be detected through the fistulous opening, and they can readily be extracted through the same channel. And here it may be remarked that when prostatic enlargement exists to such degree as to form a bar to the extrusion of urine through the internal meatus and by the urethra, it is, I believe, a better and safer surgery to preserve the fistulous abdominal opening as a natural channel, and so be able to ignore and discard the hypertrophy of the prostate gland. This really ceases to be of any importance when the patient has once learned to draw his water by his new channel. It has been said that there is a constant leakage, or urinary incontinence, by the newly formed urethra. This objection is, however, rather theoretical than otherwise. Practically it will be found that if the incision in the bladder be made on its front surface, as high up as possible, the urine will subsequently accumulate until the bladder is filled up to the level of the opening, and that no leakage can or will occur until this water level is reached. Moreover, it is often the case that before any leakage occurs the patient will experience a sort of premonition not unlike that which precedes normal micturition. He can then introduce his short catheter through the artificial canal.

Dangers of Suprapubic Method.—The vital question connected with this operation is that of its danger. Its inheritance from the past has been accompanied by a suspicion of those perils, with which before the date of antisepsis and laparotomy the incision of the belly and peritoneum was then fraught. Yet so perfect is the technique of the present suprapubic cut that the occurrence of the once dreaded peritonitis need no longer be feared. Nor is there any danger of serious bleeding, for even if the prevesical veins be injured the bleeding would only be sufficient to obscure and delay a little the later steps of the operation. The peril of shock is at a minimum, nor need it be feared, if we bear in mind that the peritoneal cavity is not opened; nor is there the shock of bleeding. The only danger which can threaten the patient must depend upon preexistent pathological conditions of the associated organs—the prostate, ureters, and kidneys. The same conditions, however, would influence equally any surgical vesical interference. Clinical experiences and the observation of results, rather than mere academic discussion, must after all be accorded their full weight in judging of the value of this operation. It is well, too, that the consensus of the opinions and operative preferences of individual surgeons should be gathered, rather than a mere bald statement of heterogeneous statistics.

My own conclusion, based upon my own cases and upon my observation of the more numerous experiences of my colleagues and friends, is that this operation is accompanied by scarcely any shock, and that it is free from peril to a remarkable degree. I have been so fortunate as never to lose a patient upon whom I had performed it. I have seen only one fatal case, and this was operated on by a most expert surgeon, under urgent conditions. The patient was a very old man, wearied by long travel and unceasing pain. When brought to Philadelphia he was suffering unbearable agony, which demanded immediate relief. The operation was one of absolute necessity, which could not be deferred. The bladder was found to be in a softened and ruined state, and the patient died two or three days afterward.

The advantages of the high operation may be thus briefly stated:

1. The ease with which it can be performed.
2. Its thoroughness, affording as it does an easy extraction of the calculus, and also the opportunity for full digital and ocular examination of the interior of the bladder. The encroachment upon the bladder cavity of prostatic growths and other tumors can also readily be detected. If the operator so decide, these can be excised or removed. If a small calculus be hidden by a prostatic bar, or by any fold of mucous membrane, it can surely be felt and taken away.
3. In fact, the high lithotomy offers a greater degree of thoroughness and opera-
tive certainty than any other method for the removal of stone from the bladder.

4. Good drainage can be effected. If desired, an assured immunity from prostatic trouble can be obtained by keeping the cut open and by the establishment of an artificial urethra.

5. The constitutional involvement is but slight, and there is little danger of shock or septic poisoning, or other general accidents.

6. The convalescence is speedy and the after cure satisfactory.

7. The operation is properly indicated at all ages of adult life, and also, as shown by clinical experience, in boyhood before puberty.

PERINEAL LITHOTOMY.

The varieties of these operations have been before the profession from time immemorial. For the last century and a half the single lateral, bilateral, and median methods have been practiced with a perfection of detail to which nothing can be added. The perils attendant upon all these operations have been fully recognized, and nothing further need be said in this direction. A perineal incision into the bladder has always been regarded as a last resort, to be submitted to by the patient in full appreciation of the possible chances of a bad result. It has ever been looked upon as a major operation, with all the accompaniments of shock, hemorrhage, exhaustion, peritonitis, and septic infection. The death-rate therefore has been high. Almost the only advantage claimed for it to-day is the dependent drainage. This, however, seems to be a questionable advantage, involving as it does a greater risk of local blood contamination from decomposing urine and pus secretions.

From the foregoing considerations it seems fair to conclude that litholapaxy is eminently the proper operation in the case of a stone, either small, or soft, or both; and where there is reason to believe that the bladder and associated urinary organs and prostate gland are not seriously diseased, and where, too, the general constitutional condition is fair. Where the contrary obtains, especially when the prostate gland is evidently largely involved in its middle lobe, and when the symptoms of urinary retention are marked by the presence of residual urine in greater or less quantities, I believe that the operation is not indicated. These symptoms, and particularly excessive vesical irritability and highly phosphatic and purulent urine, must lead one to suspect the presence of a small, rough calculus, concealed by an internal prostatic projection. In such cases it seems that the high operation is greatly to be preferred. And here it may be added that even in cases where litholapaxy seems proper, it is an operation for a trained and experienced specialist, rather than for the general surgeon. At all events the operator, whoever he may be, will do well to investigate for himself the mechanical conditions which accompany sudden bladder distention. I would thus limit decidedly the practice of litholapaxy, and turn rather to the suprapubic operation, which will have, I believe, a wider application in the future, far wider perhaps than in the past. It is, in fact, a procedure readily performed and which is devoid of great and sudden perils. As far as modern experience goes, it is free from that shock and that unexplained exhaustion which so often ambushes the operator by other methods.

I have met with many who hesitate to adopt the suprapubic operation, but I have met with none who could fortify their opposing convictions by their own clinical experience. Their disinclination for this operation would appear to be a relic of the past. I have fully shared this feeling, and I would scarcely have thought that my views could undergo so marked a change in this matter. However, I believe that suprapubic lithotomy is the preferable operation in most cases of stone, excepting for small or soft stones, and under the circumstances referred to, in which litholapaxy is doubtless indicated.

WHAT WE CAN DO FOR CASES OF SQUINT.*

BY EDWARD JACKSON, A.M., M.D.,
Denver, Colo.

In no department of medicine or surgery is it more important to accurately adapt our therapeutic measures to the requirements of the individual case. He who treats squint without painstaking discrimination leaves in his path a succession of patients disappointed or made worse by their experience with him, and who must of necessity advertise his incompetence so long as they live. Experience of haphazard operating has made the community rather shy of squint operations; al-

*Read before the Pueblo County Medical Society Sept. 19, 1899.
though where properly advised and properly performed, they are among the most reliable and satisfactory of surgical procedures.

In the first place there are cases of marked apparent squint in which actually no squint is present. We judge of the direction of the visual lines by the direction of the cornea. Usually the visual line passes through the center or a little to the nasal side of the center of the cornea. When it does so the eye seems to look properly at the point of fixation. But when the visual line passes through some other part of the cornea the eye seems to be directed elsewhere, although it may fix accurately the object looked at. About the first thing to be done for a case of apparent squint is to try the fixation of each eye separately; to find how the eye does turn when it fixes a given point, and if it really is squinting when it appears to squint.

These cases of apparent squint should not be dismissed without a careful explanation of their real condition, and the uselessness and harmfulness of applying the treatment for squint to eyes that really see normally together, and only appear to deviate. If you fail to make his condition clear to such a patient, he will pretty certainly fall into the hands of some one who will offer to do an operation and promise relief. I have known a young woman who had perfect binocular vision, with a trace of esophoria, treated by a prominent ophthalmic surgeon for a year with prisms, and an operation suggested for a supposed divergent squint, simply because one cornea was markedly displaced outward, giving the appearance of squint, although the eyes were properly directed.

**COMMENCING SQUINT.**

The time to do most good by the treatment of squint is at its beginning. The wise caution against early operation means that operation should be a last resource, not the first one. It is not that operation is capable of yielding better results in squint of long standing, but that operation is only necessary when a deviation has become comparatively permanent; and it can only be intelligently undertaken when certain points have been carefully investigated, and the influence of other measures has been faithfully tried.

No case of commencing squint should be kept untreated by the advice to wait in the hope that the child may “outgrow” it. The probability of outgrowing a squint, and the rapidity and completeness of outgrowing it, depend chiefly on the intelligent care and treatment of the case. A few squints are outgrown without any especial care. A great many more would be outgrown—that is, gradually overcome and recovered from—with proper early attention. The possibility of outgrowing it is the strongest reason for giving every case of squint the earliest attention, in order that it may not become fixed, and so mar the development of the function of binocular vision that complete restoration will become impossible.

To cut short a commencing squint the most generally effective measure is the wearing of lenses. Convergent squint commonly begins before six years of age, and hyperopia is often an important factor in causing it. Divergent strabismus, usually arising in connection with myopia, which is commonly acquired during school life, begins later. Even where the error of refraction is not the only cause, or the chief cause, of the squint, its influence at the time the squint is developing is always unfavorable, and should be removed if possible.

Prior to the development of skiascopy the exact measurement of errors of refraction was not possible until the child reached an age to respond satisfactorily to the subjective tests. Hence the correction of errors of refraction was too inexact and uncertain, at the time of commencing squint, to be of much practical value. A few cases were successfully corrected; but the results of inaccurate estimates of the refraction in other cases were such as to destroy confidence in the chance of relief by lenses. Now, however, we have in skiascopy a method of accurately correcting errors of refraction during the formative period of squint, when such corrections are of the greatest value; and such corrections should be employed in the great majority of cases. I have prescribed convex lenses, and had them worn with the greatest benefit before the age of three years. Priestley Smith has given them at the age of fourteen months. There is little difficulty in having glasses worn by very young children. The eyes can be kept under a mydriatic, and if there is a decided need for the lenses the child very quickly realizes that it sees better with them. It accepts them as a matter of course, long before its elders have recovered from their amazement or ceased to console on its misfortune. It is quite possible by the wearing of lenses until the tendency to squint has been overcome, and the function of binocular fusion thoroughly established, to render the child safe from a recurrence of
the squint, even if the glasses should not be worn constantly at a subsequent period.

In regard to lenses for the correction of squint, the rule to correct all the ametropia is imperative, and the glasses must be worn constantly. Then the mounting of the lenses must be carefully looked after. The wearing of strong lenses with the optical center of one slightly higher than that of the other, giving the effect of a prism base up or base down, might render binocular vision impossible, when the whole purpose was to render it easy and certain. Decentring and prismatic combinations may be needed to further this purpose of the lenses, to promote binocular vision.

The placing of one or both eyes under the influence of a mydriatic is commonly mentioned as a therapeutic resource in commencing convergent squint, and properly so. But it has a usefulness quite subordinate to that of lenses correcting hyperopia. It may be used in both eyes, to prevent all efforts at accommodation, with which excess of convergence is apt, at first, to be closely associated. Or it may be used only in the eye that is noticed to fix habitually, to blur its vision, and compel the patient to use the eye he is inclined to let deviate. For this latter purpose it will do no good if the vision in the deviating eye be so defective as to be worse than the other when under the mydriatic.

If atropine is used at all, it should be carefully and regularly instilled so as to keep the eye fully under its effects. The pupil may seem to be pretty well dilated, especially in a child, when there still remains a good deal of accommodative power; and the simple weakening of the accommodation may provoke increased accommodative effort, and with it increased convergence, thus doing harm rather than good. For such a purpose atropine is the mydriatic to be preferred. The brief influences of the others, with their greater liability to cause symptoms of mydriatic intoxication, render them distinctly inferior for this service.

The use of the atropine is generally but a temporary measure, to hold the tendency to excessive convergence in check, while the case is being studied and glasses adjusted; or until the child becomes accustomed to the lenses and learns to see through them, giving up his excessive efforts at accommodation. In a few cases it may be worth while to continue the use of the mydriatic longer, but generally this is the extent of its usefulness.

Next in the order of practical usefulness, of the measures generally applicable in commencing squint, is the occlusion of the better eye, the fixing eye, forcing the child to use the one which seems inclined to deviate. This will aid in developing the power of using an eye that is congenitally imperfect, and will prevent the formation of a fixed habit of disregarding the images formed in it. It is most beneficial in cases of temporary paresis of one or more of the ocular muscles, preventing the establishment of a squint before the affected muscle recovers sufficient power to insure normal ocular movements.

Ocular palsies are not nearly so rare among children as the published records might be taken to indicate. They are a good deal neglected. The child complaining of seeing things double, unless he has very intelligent or timid parents, is apt to be told not to think about such things, or to look so he will not see double; and as diplopia very quickly ceases to be annoying in young children, nothing more may be thought of the matter until a decided squint has become permanently established. Most paralytic squints tend to become partly concomitant, and it is certain that a portion of the cases that are subsequently brought to our notice as concomitant squints have such an origin.

The especial liability of diphtheria to be followed by paralysis is well understood. But often the affection of the eye muscles does not become evident until several months after the diphtheritic attack; and it may follow a mild attack that has been regarded as a simple sore throat and quite forgotten. Any indication of diplopia should be attended to. Satisfactory tests as to the condition of the ocular muscles can be made on quite young children. If there is evidence that, with apparently good eyes, the child is disposed to habitually use one and allow the other to deviate, the regular exclusion of the fixing eye, by a bandage or a closely fitting opaque shade, should be resorted to, until a careful investigation of the condition can be made and other effective treatment adopted.

The partial exclusion of one eye so that the patient will be compelled to turn the eyes in a certain direction might be of service in some cases of paretic ocular muscles; but it is doubtful if it should be mentioned among really practical measures. Certainly the importance sometimes attached to it is quite exaggerated.

It is perhaps hardly necessary to remind you that the treatment of the general condition of the patient is an important matter in com-
mencing squint. Of those cases that cannot be traced to any distinct paralysis or paresis of a particular muscle, a large proportion arise during periods of distinctly impaired health. It would look as though the extremely complex coordinations required for perfect binocular adjustments were easily overthrown or prevented, when the central nervous system was not in its best condition. Hence it may be of capital importance, while taking care to make the binocular adjustments as easy as possible, and to prevent the establishment of any vicious method of using the eye muscles, to hasten in every way the recovery from a temporary condition of depression, in which the coordinating nervous system is unequal to the tasks laid upon it.

**ESTABLISHED SQUINT.**

No case of curable squint can be regarded as absolutely established; and when our more radical measures have disturbed the accustomed condition, any of the procedures applicable to commencing squint may render important service. But there are certain methods of treatment that only become applicable when the deviation has reached a comparatively established and fixed condition.

Most important among these are operations upon the eye muscles. These operations effect a more or less permanent alteration of the relations of the eyeball to surrounding structures, and are, therefore, only justified by a false relation of corresponding permanence. Thus operation is not justified by a paralytic squint which only occurs when the eyes are turned in a certain direction, or an intermittent squint which is part of the time entirely absent. In a squint that is always present, but variable in amount, we must first by lenses, or a mydriatic, or in some other way, eliminate the variable factors before we can attack the permanent factor to the best advantage by a permanent alteration in the relations of the eyeball. Neglect of this precaution has done much to bring squint operations into merited disrepute.

I shall not now go into the technique of the squint operations, but briefly consider them in certain classes. We have first tenotomy, which seeks to lessen the influence of the tenotomized muscle upon the movements of the globe. It is at once the simplest and the easiest of our operative procedures, and yet the most likely, when improperly undertaken or performed, to cause serious permanent harm instead of benefit. It is the operation that is liable to be followed subsequently by unsightly deviation in the opposite direction.

Next we have advancement, designed to turn the eye more in the direction of the muscle operated upon. It is comparatively free from the danger of turning the eye too far, so that it will deviate in the opposite direction. But it is more tedious and difficult than tenotomy, and followed by greater reaction and slower healing.

Then we have extensions of tenotomy by the division of accessory bands; and extensions of advancement by the advancement of tissues adjoining the tendon, as the capsule of Tenon and the overlying tissues. There are also subsidiary measures like the insertion of a stitch, which is tied so as to retain the eye continuously in the desired direction. The maximum effect is obtained by doing a tenotomy on one muscle and an advancement on its antagonist.

Appropriately chosen and properly executed, there are few operations in surgery that give more uniformly satisfactory results than those on the eye muscles. Still the exact effect of a given operation cannot be certainly predicted; and the most perfect results are only attained when the operation is supplemented by other measures.

A supplementary method of practical value is practice with the reading-bar. This consists of a light strip of metal, wide enough to cut off so much of each printed line from each eye as to prevent the reading of the whole line by either eye alone. It is placed far enough from the page (two and a half or three inches) to allow each eye to see the part of the line cut off from the other. It is supported in position by a base held against the page by one thumb, the base being connected with the bar by an upright perpendicular to both.

The reading-bar is to be used when there is a continuous squint, or when, as after a squint operation, the proper coordination of ocular movements is not established. It compels fixation with both eyes for the reading of each line. If the two do not fix together, the deviating eye has to be brought up to the position of fixation each time the reading-bar prevents the fixing eye from reading farther. The tendency is to accustom the deviating eye to the practice of fixation, and to induce it to fix with the fixing eye, to avoid the interruption that would otherwise be caused in the reading.
The great advantage of the reading-bar is that it gives the required training while the patient is engaged in an ordinary occupation or amusement. Other exercises of the sort, as the stereoscope applied to the orthoptic training of the eye, are only available as special tasks quite aside from the ordinary use of the eyes. On that account they are certain to be neglected after a time, unless the patient remains under the regular supervision of the surgeon, and makes a business of perfecting the cure of his squint. The usefulness of the reading-bar is limited for the treatment of commencing squint by the common inability of such young patients to read.

An orthoptic exercise that any patient can practice for himself, and which may be of value after a squint operation, as it is in cases of ocular paralysis, is that of holding a finger or a lead-pencil in some part of the field where fixation is easy, and moving it slowly to a part where it is more difficult. Thus for weakness of the right external rectus it can be held first on the left and then moved gradually over to the right; or for failure of convergence (relative divergent squint) it may be held first at a distance and then gradually approximated to the eyes. Even a young child may be induced to engage in the game of keeping the pencil single as long as it can. When in spite of the effort the pencil appears double, the effort is given up, and the gaze turned elsewhere.

The usefulness of prisms in the treatment of actual pronounced squint is so limited that their employment need not now be discussed. They are valuable chiefly in cases of vertical squint or of paralytic squint.

I have reviewed briefly our principal resources for the treatment of squint. What can we accomplish with them? For apparent squint we can do nothing. The possessor of this defect enjoys all the advantages of binocular vision, but he suffers from a cosmetic defect, sometimes very annoying, but incurable without the sacrifice of binocular vision.

Complete permanent paralyses of the orbital muscles, whether congenital or acquired, and particularly those of muscles supplied by the oculomotor nerve, are only capable of benefit to the extent of reducing the deformity and rendering it less offensive. Fixed defects of the coordinating centers, generally having a basis of congenital anomaly, but sometimes due to an abnormal development caused by squint, are also incapable of complete relief. This class includes some of the cases of squint with so-called amblyopia exanopsia, and the rare cases of "antipathy to single vision."

Great elongation of the eyeball renders some cases of squint with high myopia also incapable of complete correction.

But after all these are set aside, there remain the great mass of cases of squint, more or less concomitant, that we can completely relieve from noticeable deformity, and to whom we can give more or less of the benefits of binocular vision. Perfect development of the power of binocular vision may not be attained in many cases of squint, yet some of its benefits can be secured for the great mass of patients.

HEROIN IN COUGH.

By CHAR. HERWIRSCII, PH. M., M.D.,
Instructor in Clinical Medicine in the Philadelphia Polyclinic; Laryngologist to the Rush Hospital for Consumptives in Philadelphia; Visiting Physician to the Nazareth Home for the Aged.

Among the newer drugs which have within a year appeared on the market, and to which the attention of physicians has been called, heroin appears to be one of the best. Dresser and Floret published their experiments with this new derivative of morphine in the Therapeutische Monatshefte for September, 1898, in which they stated that heroin not only very much modifies and quiets the cough, but also that the frequency of respiration was lessened and the inspirations prolonged. The same authors state that heroin has a more sedative effect upon respiration than morphine, and is ten times more powerful than codeine.

Leo (British Medical Journal, April 29, 1899) also discusses the value of heroin. He states that the drug has a particular action on the respiratory centers, lessening the frequency but increasing the depth of breathing. He says that its narcotic action is much less than morphine; and thus in sciatica, neuralgia, cardialgia, including the pain due to gastric nerve and muscular rheumatism, heroin did not relieve the pain, or did so only momentarily. Leo found the action of this drug exceptionally satisfactory in the various forms of dyspnea; it increases the duration of inspiration and the amount of air taken in. He cites a number of cases, among them two cases of uremic dyspnea, some of emphysema, chronic bronchitis, and asthma, and says that in all but three cases
out of thirty the results were good. He also says that heroin can be used with confidence, and will be permanently found to be a valuable remedy, in diseases accompanied by dyspnea.

During the last ten months I have used heroin in more than thirty cases, mostly with good results. In acute bronchitis I used it in adults as well as children with much satisfaction. In chronic bronchitis and in phthisis the drug has in most cases given good results, and failed in only three.

Miss W. H., aged thirteen, contracted a heavy cold in December, 1898. After administering the usual remedies, the patient had still, after three weeks, a distressing cough with tenacious expectoration. I ordered heroin, $\frac{1}{4}$ grain, three times a day. After forty-eight hours the patient reported the cough decidedly better, and the expectoration much lessened. After a week’s treatment the cough had disappeared.

M. B., a boy nine years of age, was left with a severe bronchitis after an attack of measles in December, 1898. He was given heroin in $\frac{1}{12}$-grain doses three times a day, with the same happy results.

Mrs. H. H., aged forty-three, had an attack of acute bronchitis in January, 1899. After employing hyoscyamus and codeine without very good results, heroin in $\frac{1}{12}$-grain doses was given three times a day; this eased the cough, the patient could sleep, and in a week she had recovered.

Mr. F. A. G., aged thirty-one, had an acute bronchitis and laryngitis in January, 1899. He was a business man and used his voice constantly. I ordered local applications to his throat, with inhalations, and gave him heroin in $\frac{1}{12}$-grain doses, four times a day. He reported from day to day as getting better, only complaining of a drowsy feeling. After three days the heroin was cut down to three doses a day, when the drowsiness ceased, and after ten days the patient reported himself free from cough.

I myself contracted an acute bronchitis in February, 1899, and heroin in $\frac{1}{12}$-grain doses relieved the cough promptly.

F. B., aged nineteen, suffering with phthisis pulmonalis, with a cavity in the left upper chest and much dyspnea. He is frequently troubled with a dry cough. He had formerly taken morphine in one-eighth-grain doses, or codeine in half-grain doses, four times a day. Heroin is now given in $\frac{1}{12}$-grain doses three times a day; after a few doses it relieved the cough and subdued his dyspnea.

A. P., aged twenty-seven. Phthisis pulmonalis, cavity in upper lobe of right lung. He has been in different sanatoria, and had taken for a year serum injections. Two months ago he came to me, complaining of a cough lasting the last five weeks day and night, much dyspnea, vomiting after taking food, and an afternoon temperature of 103°. At first I gave this patient codeine $\frac{1}{4}$ grain and acid hydrocyan. dilut. $\frac{1}{2}$ minim in a vehicle every three hours, with local treatment to his throat; this relieved him for three days, when he again began to cough constantly. I now ordered heroin in $\frac{1}{12}$-grain doses every four hours, which promptly relieved the cough and dyspnea, and made him drowsy. After several days the above dose was given every six hours, and he now takes that dose every eight hours, and except for a cough in the morning is very comfortable during the day. Other appropriate treatment was instituted, and on the 7th of August, when I last saw the patient, his temperature in the afternoon was 99.4°, respiration 28, pulse 92 per minute; he had gained four pounds in two months. He coughs very little and reports feeling well and enjoying his meals. He has not vomited for six weeks; bowels are normal.

At the Rush Hospital I am using heroin on a number of patients mornings and evenings in $\frac{1}{12}$-grain doses for the cough, and among ten patients in only one, after six weeks’ use of that dose, had the same to be increased.

Early in my experience I gave to a patient, Mrs. F. P., aged thirty-five, suffering from phthisis, heroin in doses of $\frac{1}{12}$-grain every four hours, but although the cough was relieved I had to discontinue the drug, as it produced sleep, the patient not being able to keep awake at any time, even after the dose was diminished.

David E., aged twenty-eight, suffering from phthisis, with extensive cavity in left chest, was given heroin in $\frac{1}{12}$-grain doses for his cough. The drug had no influence on his cough, but constipated him to such an extent that it had to be discontinued.

F. L., male, aged forty-seven, suffering from phthisis pulmonalis, last stage, was given heroin as an experiment. The patient was very comfortable with morphine in one-eighth-grain doses three times a day; this was omitted and heroin in $\frac{1}{12}$-grain doses given, which was later increased to four doses a day, and again a few days later to one-sixth-grain doses three times a day, but
without having any influence on the cough, and I had to return to morphine again.

I have in all treated thirty-five cases with heroin, but space prohibits the giving of more histories.

From the foregoing cases the following can be deduced: Heroin in doses from one-twelfth to one-sixth grain three times a day is a very valuable addition to our materia medica in acute as well as chronic bronchitis, and the cough accompanying phthisis. The drug acts well in most cases, and except in the three cases mentioned, where it did not give any benefit and had to be discontinued, the results were always satisfactory. The number of respirations of the patients taking the drug was diminished, as the charts in the hospital, and of some of the cases in private practice when such could be kept, prove the drug, after being taken in some cases for three months, except in one case, had not to be increased, and no drug habit was established. Except in one case heroin had no tendency to constipate like morphine, and in only one case did drowsiness follow its administration. No headache or disorders of the stomach resulted from the use of heroin, as is often the case with morphine. The dose is much smaller than either morphine or codeine, and very much cheaper than the latter drug, a great advantage if a drug has to be used for a long time, as in phthisis. Of late hydrochlorate of heroin, soluble in water, has come into the market, which is adapted for hypodermic use, and as Eulenburg in the *Deutsche Medicinische Wochenschrift* of March 23, 1899, reports, the same so used acts more rapidly than when given by the mouth.

---

**SOME THERAPEUTIC MEASURES OTHER THAN MEDICAMENTS.**

By W. L. Johnson, M.D.,
Clinician, Department Skins and Syphilis, and Acting Clinician Children's Clinic, St. John's Hospital, St. Louis, Mo.

The writer has no word against modern medicaments, but desires to remind others and be himself reminded of some measures, not medicinal, in combating disease and its morbid manifestations. Therapy does not mean drugs—it is broader than that.

Let us take pilocarpine, for instance. Gaskell's experiments point to the fact that it, like acids, shortens the systole of the frog's heart, renders it subsequently less and less powerful, and finally causes cessation of its action, the ventricles remaining at rest in diastole. Brunton classifies pilocarpine as a cardiac depressant and paralyzant—that is to say, the cardiac muscle is no longer capable of contraction on stimulation, either mechanical or electrical. Probably by its stimulating the terminal branches of the glandular secretory nerves we have its characteristic effects. Probably it has a central action. We have a copious diaphoresis, and frequently a marked sialorrhea. Hence there are conditions where it is indicated and used: puerperal eclampsia, uremia, and in infectious diseases such as croup, influenza, and scarlet fever—in short, wherever and whenever, theoretically, we desire elimination. But pilocarpine may be contraindicated, for it is by no means devoid of danger. Cardiac or general syncope, sudden pulmonary edema, convulsions, "strangury and sometimes retention" (Brunton), as well as dimness of vision, vomiting, and glandular swellings, have all followed its administration.

We may well resort, then, to the hot pack, steam or vapor bath, or hot-air bath, in cases requiring diaphoresis and in beginning influenza or threatened eclampsia. One of these combined with hot drinks will work the same results as jaborandi. Uremia may thus be treated, and in threatened eclampsia it is both safe and effectual.

It is now considered a fallacy to "dry up" the secretion of milk by atropine—at least by its action alone. Moreover, there are cases where it is contraindicated. Instead of giving the drug and using camphor or belladonna liniment or what not, bandage the breast with a roller bandage or adhesive strips. Massage if you will with belladonna ointment, but *massage*. The same may be said of mastitis, non-surgical: give phytolacca if you must, but massage or bandage. Pressure by the bandage is the most reliable treatment; there is none more sure in aiding nature. Pressure causes absorption; it diffuses, it rests. Its possibilities are only suggested here.

Let us take a case of pleurisy, acute fibrinous, with moderate or no fever when seen, a stitch in the side aggravated on coughing or deep inspiration, and while opium or a plaster, or both, often accomplish much, yet rest is indicated; and that rest is best secured by strapping the affected side of the chest, thus insuring rest to the part that needs it and no other, and in a manner that in no wise interferes with the secretions or excretions. You cannot constipate a man by
“fixing” half of his chest, and you can if you give opium.

There is a field, and a wide one, in which ergot is used, and yet in many instances it would be better to substitute physical means. In hemoptysis many regard this drug as not only of no value but injurious and irrational, since capillary bleeding, it is contended, is not at all influenced by ergot; and furthermore, it causes a rise of pressure in the pulmonary circulation. In these cases intermittent cold applications, sucking of ice, dry cups to the chest (or other counter-irritation), are all of service, and combined with absolute rest, the first requisite, more reliable than any medicine, except perhaps morphine.

How frequent it is that convulsions in infants may be controlled by means other than medicinal. The rectal injection of chloral or the giving of bromides, while not devoid of good, are not to be resorted to in a routine fashion, nor yet the inhalation of chloroform. Cold to the head, the warm, not hot, bath, the mustard pack, or mustard foot-bath, flushing the bowels, or even the use of an enema, are all measures easily resorted to and which promise good results. Removal of the cause, as a pin, a swollen gum, an overloaded stomach, may be remedied without resort to medicine. Pressure on the carotid (which necessitates pressure on the sympathetic)—a simple procedure—indeed—has stopped convulsions. Here again absolute quiet is indicated. Who does not know the value of quiet in strychnine poisoning, and in tetanus?

Not only are nervous symptoms favorably influenced by rest, but many other conditions; so much so that we have a “rest cure” for many ailments. In threatened abortion there is nothing comparable with rest, and while opium is frequently of service, the recumbent position with no exciting influences must always be resorted to and insisted upon. Ergot and opium are of inestimable value in these cases—the former in very small doses of a reliable physiologically tested preparation—but where there is persistent pain and hemorrhage of any consequence they are best met by a mechanical plugging of the vagina. Nor does this procedure necessarily invite abortion. Often when it is seemingly inevitable, resorting to this method, with the view of exciting contractions and causing complete expulsion, we obtain quite contrary results—the os closing, pain and hemorrhage ceasing.

While we have remedies innumerable for meeting postpartum hemorrhage, we have one that is sure, yet not appreciated by all. The physician need not have ice, lemons, vinegar, or persulphate of iron, if he will have unbroken packages of plain sterilized gauze and at once pack the uterus. Why temporize? There is no great danger—not as great as using iron solutions. Give your aseptic ergot for all that, but pack. King in his Manual of Obstetrics describes the method. It is safe, rational, and effectual. In Sajous’ Annual, 1893, Barker is thus quoted: “After having a fatal case of postpartum hemorrhage from an empty uterus I concluded that if I had used the intra-uterine tampons, as advised by Dürsssen, I might have saved the woman’s life.”

Hilton, years ago, dwelt upon the value of rest especially in diseases and injuries of the spine. To rest the brain does not of necessity mean entire disuse of the faculties. We may rest the part accustomed to work and yet be active mentally, just as we may rest an arm in a sling and yet have much physical freedom; forgetting our professional or business worries in the joy of sightseeing or the rugged, hardy pleasure of hunting, is rest. Each organ, as Hilton pointed out, appears constructed with innate powers to rest from its labor, and unless given the opportunity will be altered structurally. Thus the heart, when repeatedly subjected to great strain, as excessive exercise, fever, or constant emotional disturbance, without appropriate rest, and the liver, kidney, or stomach constantly overworked by alcoholic or other excesses, become the seat of fatty, cirrhotic, or other changes.

While there cannot be absolute there can be relative or partial rest of the heart during life, and since we know that pressure within the heart is an important factor in the production of endocarditis, our first effort in acute rheumatism is to secure reduction of this pressure by rest, whether to prevent endocarditis or, once established, to combat it. Few more important observations have been made than the necessity of consigning the agile young patient suffering from acute rheumatism to the security of perfect rest. In valvular diseases of the heart the diet, avoidance of overexertion, guarding the emotional nature, are first and paramount principles of treatment. This does not mean that digitalis, its congeners, and tonics have no place, but that with them and often without them this rational rest is indicated; witness the Schott treatment.
In convalescence of a critical nature following acute disease we must not forget a fact, pointed out by Balfour, that "some trifling exertion undertaken before the heart has had time to reaccumulate sufficient energy starts an ingarvescent asthenia from which there is no recovery." Remember in these cases, then, to insist on rest, and don't stimulate to death the unstable organism with medicines.

In no department of surgery and medicine is avoidance of, or discretion in, stimulation more necessary than in concussion of the brain—remember rest here; and in many cases of sunstroke the application of ice or cold baths is far safer and surer than anti-pyretics.

SOME CLINICAL EXPERIMENTS WITH MERCUROL IN CASES OF ACUTE GONORRHEA.

By Frederick Fraley, Jr., M.D., Philadelphia.

Among the more recent germicidal preparations which have been advocated for surgical purposes is mercuriol, an organic compound of mercury with nuclein, containing about ten per cent of mercury. It exists as a light, brownish-white, fine powder, and is soluble in water, especially when the latter is warm, but is insoluble in alcohol. Its reaction is slightly alkaline. It is employed in solutions of from one-fourth to two per cent, the diluent being normal salt solution, as this seems to add to its efficiency.

This germicide is being placed on the market by Parke, Davis & Company, and at my request they furnished me with the foregoing description, and also with a paper by Dr. Karl Schwickerath, the discoverer, from which I will quote, setting forth the advantages which Dr. Schwickerath claims for his new preparation.

Dr. Schwickerath says that the various inorganic salts of mercury, silver, and copper which have been so extensively used as antiseptics and germicides are not entirely satisfactory, owing to their irritating effect on the tissues. Not infrequently they exert such a devitalizing effect that the resisting power of the tissues is so lowered that they can no longer react to stimulus, and thus the healing process is retarded rather than advanced, defeating the very object for which these antiseptics are employed. The indolent ulcer, which so often results from the injudicious or prolonged use of powerful antiseptics, is a familiar example of this undesirable action.

"The explanation of this devitalizing effect lies in the fact that these antiseptics possess too great an affinity, chemically speaking, for the constituent parts of the animal cell, and that when an inorganic salt is brought into chemical relation with the organic components of tissue a considerable reaction takes place. For instance, if a solution of corrosive sublimate be brought in contact with a wounded surface, the metallic base is absorbed, while the acid portion of the compound reacts with the albuminous elements of the tissues, this reaction manifesting itself by coagulation."

Having these facts in view, Dr. Schwickerath thought that organic compounds of those minerals which had a lesser chemical affinity for the cell, while preserving the germicidal properties of the inorganic compounds, would be less irritating. Now it is known that some of the metallic salts will enter into chemical combination with certain proteid substances, and so it occurred to him to use nuclein, a nucleo-albuminous substance found in the nuclei of animal cells, for his experiments, as this, being a cell product itself, would not be so likely to cause reaction.

As a result of his experiments Dr. Schwickerath has produced soluble organic compounds between the salts of mercury, silver, copper, and iron, and the proteid nuclein, to which he has given the names mercuriol, nargol, cuprol, and ferrinol, and of which mercuriol, as might be expected, seems to be the most powerful germicide.

Dr. Eugene Smith, of Detroit, in a paper read before the Detroit Medical and Library Association, reported the results of his use of mercuriol in diseases of the eye and ear, which were most favorable. A short abstract of this paper may be found in the Journal of the American Medical Association of March 4, 1899, page 501.

Dr. Burtenshaw, of New York, in reporting a case of exudative pericarditis, in the course of which a very severe cystitis arose, speaks very favorably of irrigations of mercuriol, which almost immediately relieved the patient after all other remedies had failed, and which within four days completely cured the cystitis. (See Medical News, March 11, 1899, page 292.)

Up to the present time (May, 1899) I know of no other reports on the use of mercuriol.

The ideal injection for acute gonorrhea is
one which, while exerting a powerful germi-
cidal effect, would at the same time soothe
the inflamed mucous membrane, and add to
its resisting power; but as yet, unfortunately,
no such valuable remedy has been discovered.
The injections most employed are potassium
permanganate and silver nitrate in weak so-
lutions, but they have not proved themselves
uniformly satisfactory, often causing decided
irritation, and failing to materially influence
the course of the disease. If, as is claimed,
mercurial is a powerful antiseptic and does
not irritate or devitalize the urethral mucous
membrane, a valuable drug has been found
for genito-urinary work.

In the cases of gonorrhrea which were treated
with mercurial the formula at first uniformly
prescribed was a half-per-cent solution of
mercurial in normal salt solution, to be used
as an injection. Later it was found advisable
in some of the cases which showed a tendency
to linger to use a one-per-cent solution, and
in one or two cases a two-per-cent solution
was prescribed without causing any symptoms
of inflammatory reaction. The one-half-per-
cent solution is equivalent to a 1:2000 solu-
tion of mercury, a much stronger solution
than would possibly be borne of the bichlo-
ride; and in fact I have injected into a
healthy urethra a five-per-cent solution of
mercurial, equivalent to a 1:200 solution of
mercury, without causing more than a tempo-
rary tingling and slight burning sensation,
which passed away in the course of less than
an hour. It would seem, though, that it is
never necessary to use a stronger than a two-
per-cent solution, which apparently is quite
powerful enough, without producing any dis-
agreeable sensation. In but one case did a
patient complain of the injection causing
more than a momentary smarting.

The patients were instructed to inject
every two hours, to hold the injection in for
two minutes, and to report every day at the
dispensary for microscopic examination
of their discharges. These instructions they
did not always follow, and it was with diffi-
culty that they could be induced to return
to the dispensary at all regularly, often re-
maining away for several days or even a week
or more. In the latter cases they would usually
say that they had felt perfectly well during the
interval and not infrequently stopped their
injections, only seeking the dispensary again
when the discharge recommenced, owing to
indiscretion or neglect. Four of my patients
never returned, and another came back but
once, reducing my number of cases under ob-
servation throughout the disease to fourteen.
In order to discover if possible why these men
had never come back to the dispensary, I en-
deavored to look them up, and succeeded in
finding only one of my recreant patients. I
learned from him that he did not come back
simply because he had had no more trouble
after his supply of mercurial was exhausted,
and had no need for further treatment. On
looking up my notes on this case I found that
on his visit to the dispensary he had a pro-
fuse purulent discharge with gonococci pres-
ent in the second degree—that is, in fairly
large numbers—and was given the usual half-
per-cent injection. Of the other similar cases
I have no record, and though it would be
quite unwarrantable to form the conclusion
that they were equally fortunate, yet it leaves
this as a possible explanation of their non-
appearance.

Of the fourteen cases which I had an op-
portunity of treating for a somewhat longer
period, six were entirely cured, being in all
respects normal; three practically cured; three
distinctly improved; and two were distinctly
not improved, but were worse when they
were taken off mercurial than when they were
put upon it. In explanation of the foregoing
statement, it is necessary to understand what
we mean by practically cured.

The dispensary patient comes for the re-
lied of one or both of two symptoms:

1. The urinary symptoms.
2. The discharge.

The discharge only annoys the patient when
it is of sufficient quantity to soil his clothes,
and if we reduce it so that there is only the
so-called “morning drop,” and relieve his
urinary symptoms, he will consider himself
perfectly cured and will not revisit the dis-
ensary until he is again unfortunate, or
until some indiscretion on his part lights up
the old complaint.

In the cases I classify as “practically
cured,” there had been no gonococci present
in the discharge for at least three visits, and
the discharge itself was reduced to the
“morning drop.” Urination was of course
normal in all of these cases when last under
observation.

Before drawing my conclusions I intend to
present a few cases, copied directly from my
note-book, illustrating those in which the
treatment was not successful as well as those
in which the best results were obtained.

Case I.—The first that came under treat-
ment was F. R., aged thirty, motorman, who
came to the dispensary on March 14, suffer-
ing with acute gonorrhea. His previous history showed four or five attacks, the last one about a year ago. The history of the present attack was that he had been on a spree a week before, and a few days afterwards the discharge appeared. The discharge was quite profuse, mucopurulent, and gonococci were present in the first degree—i.e., in large numbers. There was no increased urination, but the patient complained of chordee. Mercurol was prescribed, one-half per cent in normal salt solution, to be injected every two hours.

March 17. Urine clear; no symptoms; scanty discharge; no gonococci. Injection does not smart.

April 1. Very scanty discharge, no gonococci, but complains of frequent urination, without tenesmus.

April 14. Has had no discharge for some time, and has no symptoms. Says he feels cured. Mercurol stopped and patient given zinc chloride gr. iv to oz. iv to tone up urethra.

The patient I think we may fairly say was cured exactly one month from instituting treatment.

CASE II.—C. D., aged twenty-three, student. First seen on March 16. Previous history showed attack of gonorrhea two years ago, which lasted three months. The present attack had lasted several weeks, and had had an incubation of four days. On examination a scanty mucopurulent discharge was found. No history of chordee or arder urine. Gonococci present, second degree. Mercurol injection, one-half per cent every two hours, prescribed.

March 18. Very scanty discharge, no gonococci.

March 23. No discharge, no symptoms.

March 30. No discharge, no symptoms.

April 6. A very slight mucous discharge, no gonococci present, but many epithelial cells, showing that repair was well under way. No urinary or other symptoms. This case lasted only three weeks after treatment was instituted, and may be said to be practically cured.

CASE III.—J. S., twenty-four, student. Seen March 23. Previous history showed several attacks. The present attack was of a few days' duration, and the patient had a moderate purulent discharge with very abundant gonococci, first degree. Had no urinary symptoms or chordee. Given a half-per-cent injection of mercurol every two hours.

March 25. Very scanty discharge, slight ardor urine, but the injection does not smart. No gonococci in discharge.

April 5. No discharge, no urinary symptoms.

April 14. No discharge except morning drop; a few shreds in the urine; no gonococci.

April 20. No discharge for several days; urine clear; no symptoms.

The patient was loud in his praise of mercurol and declared it to be the best remedy he had ever used. His entire attack lasted only about four weeks.

CASE IV.—This case will serve to illustrate the severe tests to which remedies are subjected by intractable patients. O. B., twenty-three years old, a laborer, came into the dispensary on March 28 with a profuse mucopurulent discharge. His history told of several previous attacks, and the present attack had lasted a week, coming on one day after exposure. He complained of arder urine and chordee, and the two-glass test showed a posterior as well as an anterior urethritis. The discharge contained gonococci in the first degree. An irrigation of mercurol, one-half per cent, was given, but no hand injection, and patient was told to report next day.

March 29. No posterior urethritis, the second glass being clear, but the discharge was still profuse, and gonococci abundant. Mercurol in half-per-cent injections prescribed.

March 31. Still a profuse discharge; gonococci, second degree. Mercurol raised to a one-per-cent solution.

April 4. Discharge continues, but is scanty; gonococci present in third degree. The patient acknowledges excesses in drink during the past week. No urinary symptoms.

April 6. Very scanty discharge, very few gonococci; no other symptoms.

April 13. Very scanty discharge; no gonococci; numerous epithelial cells. Given a two-per-cent injection of mercurol.

April 17. Profuse discharge, but urination normal, and no gonococci in discharge. Patient admitted having been off on a drunk.

April 22. No discharge at all; no symptoms; has been having sexual intercourse. Continued two-per-cent injections.

This case was certainly much benefited, though it is doubtful whether it could be considered cured owing to the patient's indifference, his excesses being sufficient to keep up the discharge notwithstanding treatment.

CASE V.—W. G., student, twenty-three
years old, came for treatment on March 28. Past history told of an attack of gonorrhea three years ago. His present condition had lasted three days, after an uncertain incubation. He had a moderate discharge, containing gonococci, first degree, but had no urinary symptoms or chordee. Put on half-per-cent mercurial.

March 30. Discharge has almost completely ceased; gonococci present in third degree. Patient has no unpleasant symptoms, and says the injections do not smart.

April 3. Very scanty discharge; only one or two pus cells containing gonococci discovered in the discharge. Patient says he feels perfectly well.

April 11. Patient has a very profuse discharge, soiling his clothes, but no other symptoms. The mercurial injections were raised to one per cent. No gonococci found.

April 13. Discharge entirely stopped.

April 17. The two-glass test shows a total urethritis with probable cystitis; the patient is urinating every ten minutes, and has arder urinae and vesical tenesmus.

Patient denied excesses, but said his occupation kept him on his feet every day for eight or ten hours. His discharge had ceased, and none could be obtained. An irrigation of half-per-cent mercurial was given, but next day showed no improvement, and the irrigations were changed to potassium permanganate, under which improvement was immediate and uninterrupted. In this case mercurial cannot be said to have accomplished much, although the discharge was stopped and the gonococci destroyed, for when the urethra and bladder were involved it seemed to have no effect whatever. It is quite possible that a stronger injection, two per cent for instance, might have yielded better results, but the patient was suffering so acutely that it was not deemed justifiable to continue mercurial, when it did not seem to be doing any good.

Case VI.—H. W., twenty-one years old, came to the dispensary on March 30 with an exceedingly profuse purulent discharge, swarming with gonococci. It seemed as though each cell was crowded to its utmost capacity with the microorganisms, none escaping infection. His previous history was negative, and regarding the present attack he gave ten days as the duration and two weeks as the period of incubation. He presented no urinary symptoms, nor had he been troubled by chordee.

April 1. Discharge about the same; gonococci still present, first degree. The injection does not smart and urination is normal. Mercurial injection raised to one per cent.

April 3. Two-glass test shows a total urethritis, and patient complains of arder urinae and vesical tenesmus. Gonococci are still present in the discharge, though only in the second degree, the discharge being scanty.

The injections were stopped temporarily, and an irrigation of mercurial one-fourth per cent was given, and copaiba and sandalwood capsules ordered by the mouth. The irrigations were continued daily, and the patient's condition rapidly improved. On April 6 I have the following note:

Patient much better; no arder urinae or tenesmus; a scanty discharge, mostly mucus, containing a few pus cells with gonococci, third degree, and some epithelial cells, showing that repair had commenced. Daily irrigations continued.

April 7. Still a slight discharge, but no gonococci detected in it. The urinary symptoms are absent. Injections renewed.

Patient did not return until April 10, when he came back with a profuse discharge and posterior urethritis, and a few gonococci present in the discharge, but without presenting any urinary symptoms. An irrigation of half-per-cent mercurial solution was given, and repeated next day.

On April 12 the patient returned in great distress with a profuse discharge, and a history of being obliged to urinate every few minutes, with great arder urinae and vesical tenesmus. He was given a half-per-cent mercurial irrigation, which treatment was continued for two or three days without producing any decided change in the patient's condition. Upon changing the treatment to irrigations of potassium permanganate, the patient began to improve, and in four or five days returned to nearly a normal condition, his discharge having stopped and his urinary symptoms being relieved.

This case was remarkable in two ways: First, the extreme virulence of the infection, and secondly, the apparently well advanced cure on April 7, being followed by the severe posterior urethritis on the 10th, which failed to respond to the mercurial treatment. The patient strongly denied any injudicious act which might have caused a relapse, and as he had been especially warned to take care of himself, I have no reason to doubt his statement. A possible explanation may be
based on the fact that the primary infection was so severe that the bladder itself might have become infected, and the condition have remained latent during the period of irrigations, and started up when these were discontinued. The possibility of a cystitis complicating the second condition is also brought out by the fact that the first posterior urethritis, with pronounced urinary symptoms, yielded promptly to the mercurial injections. I have no other explanation to offer for the apparent failure of mercurial in this case.

In forming a conclusion of the value of mercurial in these cases of gonorrhea, a few figures will, I think, be the best way of making clear the results obtained. Cured, six, or forty-three per cent, in less than four weeks; practically cured, three, or twenty-one per cent, in three weeks; distinctly improved, three, or twenty-one per cent, in sixteen days; not improved, two—both of these cases were temporarily much benefited. A total of twelve cases, or eighty-five per cent, benefited by mercurial.

Immediate effect on discharge within forty-eight hours: Stopped it completely in three, or twenty per cent; lessened considerably in seven, or fifty per cent; not perceptibly lessened in four. An improvement in seventy per cent.

The effect of mercurial on the urinary symptoms was prompt, and complete relief in all except the two cases reported as failures, and in these it relieved the original conditions, though it failed in the relapses.

The average duration of treatment was as follows: In those cured, twenty-six days; in those practically cured, twenty-one days; in those improved, sixteen days. Had all the cases been willing to be treated twenty-six days, perhaps the percentage of cures would have been greater.

The best results were in the cases with simple anterior urethritis, and in the cases either of short duration (two to four days) or of comparatively long duration (ten days to two weeks), the explanation of the latter being that the disease had already exhausted some of its virulence.

In those cases which involved the posterior urethra the results were not so good, but this may be due to having used the remedy in too weak solution. Judging, however, from the rapid improvement of these cases under the use of potassium permanganate we may fairly say that the latter is the better agent for irrigations, while mercurial is superior for injections.

It would seem, however, that an unirritating remedy which has cured patients of gonorrhea in a period averaging less than four weeks is one that is not to be despised, remembering that the length of treatment in the hands of good physicians averages six weeks before a complete cure is effected.

**BILATERAL CHRONIC INTERSTITIAL MASTITIS CURED BY OPERA-
TION.**

**BY EDWARD MARTIN, M.D.,**
Surgeon to St. Agnes, Philadelphia, and Howard Hospitals.

The subject of this report—a teacher, thirty-eight years old—of sound parents and without family taint, had been perfectly well till the early part of 1889, when she began to suffer from a dull pain, referred to the middle of the sternum, and sufficiently severe greatly to disturb her health and to interfere with her vocation. This pain was always worse at the menstrual epoch. At times it would be stabbing and lancinating in character, and shoot down the right arm into the fingers. In these most severe manifestations it was attended by slight dyspnea and marked pallor. It was diagnosed as angina pectoris by her attending physician. The breast gradually grew harder, but exhibited no nodulation of any kind; nor were the lymphatic glands in the axilla affected. The constant pain did not seem to be in the breast, though the latter was excessively tender on palpation. The patient steadily lost in weight, became anemic, and exhibited the typical facies and neuroses of one harassed by a constant pain. She had been subjected to all manner of treatment.

Gout, rheumatism, and syphilis had all been suspected, and a thorough course of appropriate therapeutic means had been tried. The symptom became steadily worse, so that in September, 1895, I removed her right breast, together with the axillary and subclavicular glands. This was followed by an immediate cessation of all pain. The section of the breast showed that it was almost completely transformed into scar tissue. No cysts were apparent anywhere, and but little of the normal glandular substance could be detected. The relief from pain lasted for four months. It then returned, but was referred to the left shoulder and arm, running down into the little and ring fingers. It grew steadily worse, was associated with exquisite
tenderness and increasing induration of the breast, and was undermining her general health. At the end of February, 1896, I resected the left breast, not opening the axilla; sections showed the same fibroid changes which were so marked in the other breast. There was immediate and entire relief from pain, and it has been permanent, since I have seen the patient within three days of this report. She has gained over fifty pounds, has been in perfect health, and has not lost over an hour's sleep or an hour's work in the last four years.

The etiology seems extremely obscure. Neither before nor since the attacks of pain have there been any manifestations of a gouty or rheumatic diathesis. There is no history of trauma, no signs or symptoms of syphilis.

The differentiation of this affection from mastodynia was dependent rather upon the induration than upon any other symptom, since the patient, being much wasted by her long suffering, was typically neurotic in appearance.

The distinction from malignant disease was somewhat difficult. The nipples were retracted, but the skin was not in the least adherent, nor were the axillary glands involved. This differential diagnosis—from malignant infiltration—was not made at the time of the first operation, though it was suspected for the reasons just noted, and because the hardening was general and no nodules could be felt. It was not till examination of the sections showed a mass of almost pure fibrous tissue that cancer was positively excluded.

The excellent effect of the double operation upon the general health makes the case worthy of record, since we have become habituated to a variety of surgical interference, practiced upon neuritic women, based upon obscure physical signs and resulting in no permanent benefit to the subjects.

ANESTHETICS AS A CAUSE OF PARALYSIS.

He who upsets an erroneous doctrine sometimes performs as important a service as he who establishes a new one. Such a service seems to have been performed by Mally, who has made a study of thirty-six cases of paralysis such as authors have been inclined to impute to anesthesia (Revue de Chirurgie, July). In ten of them he finds there was a central lesion that accounted for the paralysis; six of them were hysterical; seventeen others he classes as peripheral, and proceeds to investigate them seriatim; and the three remaining cases he sets down as reflex. It is noteworthy that of the seventeen peripheral cases, eight were observed by the author personally, and perhaps it was that fact that led him to make the investigation.

Mally rejects the idea that there is any connection at all between anesthesia and the hysterical and reflex paralyses. Those of central origin may be due indirectly to the anesthetic, which in a purely mechanical way leads to the rupture of a blood-vessel in the brain. The peripheral paralyses, which are rather frequent, are always, he finds, due to compression, and the anesthesia has only this to do with them, that it favors involuntary or accidental compression of nerve trunks or the roots of the brachial plexus in the course of an operation. There is no evidence, he says, to show that the toxic or depressing action of the anesthetic has anything to do with giving rise to paralysis, and any such action on the nervous system is only hypothetical.

As regards the treatment of these paralyses, it is both preventive and curative. During anesthesia the patient's arms should not be forcibly drawn up, and care must be taken that none of the limbs are allowed to hang over the edge of the operating table or suffer compression by the weight of the patient's body or by any ill-placed constricting band. As to the curative treatment, cases of central or hysterical origin present no different indications from those afforded by such paralyses in general. The peripheral paralyses due to compression may be treated with advantage by the ordinary procedures of localized faradization, and they should be applied as soon as possible. When the reaction of degeneration is present, however, localized electrization must be avoided. The wasting of muscles about the shoulder-joint that is apt to result from paralytic immobilization may be prevented by resorting early to passive motion of the joint. The grave reflex paralyses should not be treated by localized electrization, but the reflex irritability of the spinal cord may be moderated by sedative applications of static electricity, by the "electric wind," and, if it is indicated, by revulsion over the vertebral column by means of friction and sparks.—New York Medical Journal, Aug. 19, 1899.

Leading Articles.

A NEW HYPNOTIC.

In that portion of the Gazette devoted to Progress will be found an abstract of a recently published valuable paper by Houghton and Aldrich about a new hypnotic substance known as chloretone, which is trichloro-tertiary-butyl-alcohol.

As set out in that abstract, this substance has already proved itself valuable in producing sleep in cases of nervous insomnia, in relieving nervous irritation, and in acting as a gastrointestinal sedative, allaying irritation rather than producing it, as does chloral. It gives comfort and rest without producing any of the disagreeable effects of morphine.

If their researches are duplicated by others, it would seem probable that chloretone may be found of value as a distinct analgesic, thereby differing again very markedly from chloral, which substance is only pain-relieving when given in sufficiently large doses to be distinctly depressing to the circulation.

On the few occasions in which we have had the opportunity of administering chloretone it has produced excellent results. In one instance of cardiac distress complicating parenchymatous nephritis and associated with marked insomnia, the administration of twenty grains of chloretone in the early evening produced comfortable sleep. In another case of gastric carcinoma it seemed to give the patient much relief, and still again, in a case of nervous cough, it seemed to act as a reflex sedative very effectually. The dose of chloretone varies from ten to thirty grains, and it is best given in small sugar-coated tablets of three grains each.

A HEROIC TREATMENT FOR SCIATICA.

Some of the readers of the Therapeutic Gazette may remember quite a long time ago there appeared a Progress item in our columns in which the results obtained by a Russian clinician in the treatment of sciatica by the application of hydrochloric acid were detailed. Since then a few of the medical journals in this country and abroad, chiefly the latter, have also contained reports of the institution of this method in obstinate cases of this intractable affection.

The latest instance of this character to which we have had our attention called is the report which is made by Dr. Purdee in the Australian Medical Gazette of August 21, 1899, in which he tells us of the results which he has obtained in a number of cases in which he has employed this method. After giving some of the literature on the subject, which is by no means voluminous, and pointing out that Gennates, a Frenchman, was perhaps the first to introduce this method, he tells us that in his own cases he painted pure hydrochloric acid along the course of the nerve and dressed the burn produced in this way with zinc ointment, afterward bandaging the leg. This one application gave the patient great relief. In other cases it was necessary to make two or three applications during a period of a fortnight, but he points out the fact that in some instances the superficial pain and discomfort are so severe that it is necessary to open the blisters which are produced and dress them with powdered opium.

From Dr. Purdee's experience it would seem that this method of treatment is not only efficacious but unusually rapid in its effect. Naturally, the lesions which are pro-
duced in the skin are very considerable, and it may be regarded as an exceedingly severe form of counter-irritation, more closely allied, perhaps, to the old form of cautery than the more superficial forms usually produced by the electric cautery which is used to-day. Indeed, the results produced by the application of strong hydrochloric acid must be as severe and deep as those caused by the at one time popular moxa.

While Dr. Purdee recognizes the fact that the treatment is heroic, he points out that most patients will submit to almost anything in preference to the agonizing pain of the neuritis, and he believes that the pain of the application of the acid is less than that which accompanies acupuncture.

Personally we believe that this form of treatment is not justifiable until all other methods have been tried without good results, and also that it is indicated in those patients with true sciatic neuritis rather than in those cases which are instances of sciatic neuralgia.

If any of our readers have cases in which they decide to try this method of treatment, we should be glad to hear of the results they obtain, whether they be favorable or unfavorable.

PHOTO THERAPY.

Several years ago it was announced by Dr. Finsen, of Copenhagen, that he had devised a method of treatment for the eruption of smallpox by means of the employment of the chemical rays of solar light. His treatment of the inflammatory skin conditions characteristic of smallpox was based upon the fact that the chemical—that is, the blue, violet, and ultra-violet—rays of light are capable of causing an inflammation of the healthy skin, and therefore would be capable of still further aggravating inflammations which already existed. His idea was that if these chemical rays could be excluded, inflammatory and suppurative conditions could be to a great extent decreased or set aside; and recently he has gone still further and suggested that we employ these chemical rays for the purpose of treating superficial diseases of the skin dependent upon various forms of infection by concentrating the chemical rays of light upon the part. The so-called scientific basis for this proposition is that the chemical rays of light are known to possess bactericidal properties, that they are also known to cause distinct changes in the healthy skin, and finally, that these rays are known to be able to penetrate the skin.

While it is known that sunlight in general possesses distinct bactericidal properties, it is another question as to whether these properties depend upon the various rays of light as a whole, or whether only certain of the rays exercise this influence. Finsen believes from his researches that it is the chemical rays which are chiefly responsible for the destruction of microorganisms, and he finds that while the blue and violet rays possess this power especially, on the other hand the red, yellow, and green rays are useless. Therefore it is evident that for the greatest possible bactericidal influence we must have these rays to the entire exclusion of others if possible.

Finsen concentrates the light by means of an apparatus which consists of a lens about twenty to forty centimeters in diameter, composed of a plain glass and a curved one, and between these two disks there is a bright blue ammoniacal solution of copper sulphate. As the result of introducing the blue liquid instead of using solid glass, a considerable cooling of the light is obtained, the water absorbing the ultra-red rays, and the blue color excluding a considerable amount of the red and yellow rays, which is advantageous, as it is known that these three varieties of rays have strong heating properties, and as already stated, that their bactericidal properties are scarcely worthy of consideration. While these rays, therefore, are excluded by this apparatus, the blue, violet, and ultra-violet rays are but slightly impaired. The sunlight should be perfectly clear, not diminished by cloud or moisture in the air to any greater degree than is found on perfectly clear days, and is to be directed upon the part of the body which is diseased. In cases where it is not possible to employ sunlight, the electric arc light has been employed with a special apparatus. Even with the precautions that we have named there is danger of burning the skin with the heat rays, and therefore a small apparatus much like that which is used by naturalists in studying small marine animals on the circulating stage of a microscope is employed. This is placed upon the skin, and a small current of water continually circulates through it, while the pressure which the disk exerts upon the skin renders the part anemic, and therefore the chemical rays penetrate it much better than they would do otherwise. The area of skin which Finsen has treated daily is about one and one-half
centimeters in diameter, and as a result of the treatment it reddens, swells, and a blister may form; but actual local death has never taken place in his experience. A different area of skin is usually treated each day.

Finsen tells us that he has treated 350 cases of lupus vulgaris by this means, and as a result of such treatment he is of the opinion that this method affords more satisfactory results than any other which has been presented to us so far. So, too, in lupus erythematosus he has obtained good results, although, of course, the number of his patients has been very much less than in lupus vulgaris. Seven cases of alopecia areata have also been treated by this means, and as these are all manifestations of superficial skin infection, he believes that a wide therapeutic field has been opened to us. Certainly the apparatus is not so costly as to be out of the reach of physicians who frequently meet with these conditions, and while it behooves us to regard with some suspicion such novel and unusual methods of treatment and wait until they have given undeniable proof of their advantage before indorsing them, we have thought the matter of sufficient interest to bring it before our readers in this editorial note. A full description of Dr. Finsen’s method, as described by his assistant, Dr. Bie, of Copenhagen, will be found in the British Medical Journal of September 30, 1899.

THE TEACHING OF PHARMACY IN MEDICAL SCHOOLS.

With the continual advances which are being made in the methods of teaching the various branches of medical study, many questions naturally arise for the consideration of those who are engaged in presenting to students information which will qualify them to be successful practitioners of medicine, and in the early days of the students’ career it is an important point to decide how much pharmaceutical information should be presented to the medical student for his assimilation.

Years ago there can be no doubt that a considerable amount of information of this sort was of inestimable value to the practitioner, particularly to one that intended to follow his profession in the country districts. It was necessary for him to know the appearance of growing and dried medicinal plants, and it was also necessary that he should prepare from these plants the various medicaments which he knew by experience would prove useful in his practice. To-day this function of the physician both in the country and city has become entirely obsolete. The manufacturing chemist provides each practitioner with official products in solid and liquid form at small cost and of such reliability that it is futile for an individual to attempt the preparation of medicines for himself. For this reason a certain amount of the pharmaceutical information heretofore imparted to students is no longer necessary, and the facts which he wishes to know deal rather with finished products than with crude materials. It is important to the physician of to-day that he should know about pharmaceutical and chemical incompatibility; that he should not prescribe fluid extracts in watery solutions; that he should not order salts to be dissolved to the point of saturation in any of the official waters which already have in solution a certain amount of medicinal substances; that he should not order such large quantities of bulky materials placed in pills that these pills become boluses too large to be swallowed. In other words, he must know enough about pharmacy to be able to write with ease a prescription which will not only contain the ingredients needed by his patient, but which are capable of being put up in such a form as to be easily taken and to impress the patient with his ability to compound medicines. For this reason it is necessary that he should have a working knowledge of the means by which each one of the official preparations of the U. S. Pharmacopoeia is prepared, and there is no better way of teaching him this than by allowing him to prepare a representative of each class during the early days of his medical college career. The mere manipulation fixes the method in his mind more firmly than any description or book study can do, and prevents him from making those ludicrous and oftentimes embarrassing errors which are met with by those who have not been fortunate enough to have such training in their student days.

Beyond this amount of pharmaceutical teaching we do not believe that it is the function of the medical college to go. If a physician desires to be thoroughly equipped as a pharmacist, he should gain such information from a college of pharmacy, for a full grasp of the character of information which we have outlined will certainly be sufficient for his necessities as a practitioner of medicine.
STERILIZATION OF THE SKIN.

Aside from the thorough mechanical cleansing with brushes, soap, and hot water, which is the basis of all the methods practiced for the sterilization of the surgeon’s hands, there is a wide divergence of opinion as to the best way in which this end may be obtained. There is, moreover, much evidence to show that a thorough sterilization, and one which will last throughout a long operation, is not certainly attained by any of the methods commonly in use, and indeed is theoretically not attainable.

Of the chemical agents employed for the purpose of destroying microorganisms which have not been removed by mechanical means, alcohol, carbolic acid, and bichloride of mercury are in commonest use. Führinger states that alcohol used alone, without either carbolic acid or corrosive sublimate, is much more efficient than when these agents are combined with it.

Senger (Arch. f. Klinische Chirurgie, 59 Band, 2 Heft) shows that in so far as the staphylococcus aureus is concerned alcohol exhibits in culture media, at the most, simply an inhibiting effect, which is distinctly more marked in a fifty-per-cent solution than it is when absolute alcohol is used. When, however, alcohol is rubbed upon the porous skin which has previously been softened by water and an alkaline soap, it is not unlikely that it may form antiseptic combinations much more potent than the drug itself, analogous to formalin, which is produced by oxidation of methyl alcohol, thus explaining the fact that in spite of laboratory findings alcohol is an excellent disinfectant for the hands.

The addition of carbolic acid to the alcohol forms a phenol-ether of weak antiseptic power, thus explaining Ahlfeld's and Mikulics's findings to the effect that hands treated with alcohol and carbolic acid were much richer in germs than those treated by alcohol alone. Experiments with culture media showed that germs which were destroyed by a five-per-cent watery solution of carbolic acid grew richly when treated with a five-per-cent alcoholic solution of the same drug.

On the basis of both laboratory experiments and clinical experience Senger holds that the reaction method of skin disinfection yields by far the best results. By the term reaction method he designates the use of a series of chemicals which, when brought into contact with each other, undergo a reaction, with the production upon the skin, and in a nascent and hence more potent form, of antiseptic substances.

By the use of potassium permanganate, hydrochloric acid, and sulphurous acid there are formed free oxygen, chlorine, and sulphuric acid, each a prompt and energetic antiseptic. Moreover, the drugs used to accomplish the necessary reaction are in themselves potent antiseptics. Sulphurous acid seemed to act more actively and effectively than hydrochloric acid, which in turn is much more efficient than potassium permanganate.

The method of applying this reaction disinfection is as follows: The skin is first brushed for five minutes with an alkaline soap and water as hot as can be borne with comfort. It is next brushed for two minutes with weak alcohol (fifty per cent); next for two minutes with a warm two- to five-per-cent solution of hydrochloric acid; next for one minute with a half-per-cent solution of potassium permanganate; finally, with an eight-per-cent watery solution of sulphurous acid until the manganese coloration has entirely disappeared. This requires but a few seconds.

To determine the thoroughness with which the skin was disinfected by this method, Senger excised small pieces and placed them in culture media. Of twenty-four cases thus treated, six showed growths, giving seventy-five per cent of successes. Santer, who applied a green soap poultice for one hour, followed by brushing with alcohol, a five-minute rubbing with green soap, a one-minute rubbing with alcohol, a one-minute rubbing with three-per-cent carbolic solution, and a one-minute rubbing with 1-to-2,000 corrosive chloride solution, failed in about seventy per cent of his cases; while Lauenstein, who repeated his washings for several days, employing in the meantime wet bichloric compresses, failed in forty-three per cent of his cases.

A method similar in principle, but differing from the facts that sulphurous acid is not used at all, the permanganate is in much stronger solution, and oxalic acid is substituted for hydrochloric acid, has long been employed at the Johns Hopkins Hospital, and because of the admirable clinical results following its use, has become popular in this country. The addition of sulphurous acid would seem of service, since it is cheap, does not irritate the skin, and is in itself a powerful antiseptic, at least in so far as pus germs are concerned.

A great advantage of these reaction methods depends upon the fact that they are
infinitely less irritating than carbolic solutions of adequate strength, and to many persons are even less irritating than the corrosive chloride solutions which are commonly employed. Any method which leaves the skin of the hands fissured and chapped makes subsequent disinfection difficult if not impossible.

The ultimate solution of the difficulty attendant upon hand sterilization will, with little doubt, be dependent upon the general adoption of a thin rubber operating glove. The skin of the operative area will, however, be a possible source of infection till a method of destroying the deeper-lying germs has been devised more potent than any now employed.

Reports on Therapeutic Progress

ON THE SAFETY OF LUMBAR PUNCTURE IN CHILDREN.

In an editorial on this topic Pediatrics, in its issue of July 1, 1899, does well to point out that whenever a new operative procedure promises well, both as a diagnostic and therapeutic resource, and is well adapted for routine employment because of its technical simplicity, our wonder, excited at first because such a contribution to progress was not made long ago, becomes doubly great when we perceive how little headway has been made by the profession in doing justice to the innovation. The operation of lumbar puncture, devised by Quincke in 1891, has by no means become a popular procedure despite its many enthusiastic advocates. It is very evident that the technical difficulties, slight though they be, or a belief in the meddlesome and dangerous character of this form of operative interference, is held to more than offset the possible benefits which this operation might confer upon diagnosis and therapy. In revising the study of this subject to date, the fact must not be ignored that the operation of lumbar puncture has an independent relationship to the science of pediatrics. It is quite probable that in the case of adults the technical difficulties may be considerable, the field of usefulness circumscribed, and the danger of accident great, when compared with the results of pediatric practice.

Pfaundler, working in the clinic of Professor Escherich, of Graz (where so many important contributions to pediatrics have been made), has recently completed a series of 200 lumbar punctures in children. With regard to the safety of the operation, he reports no serious accidents, while pain, hemorrhage, and danger of infection proved to be insignificant. A review of the literature assures him that other observers have likewise been satisfied with the results which they have obtained in children. Mishaps of any sort seem to be isolated and not inherent to the operation itself. Pfaundler states that owing to the superficial position of the vertebral arches in the child, together with the relatively greater spaces between them, puncture is readily effected. The lowest interspace, or lumbosacral hiatus, is the locality to be chosen for the puncture. The original puncture should always be made with the child sitting erect, in order to tap the lowest point of the column of cerebrospinal fluid, and thereby to secure a representative drop of sediment. The serious accidents which have been reported in connection with puncture have either happened to adult patients or have been due to intentional puncture into the ventricle, which is a very different operative procedure from tapping the subarachnoid space.

So far as the utility of lumbar puncture is concerned it may be said that this operative procedure has a double field of usefulness, as it not only aids materially in diagnosis, but fulfils therapeutic indications as well. Under the head of diagnosis, the first step, according to Pfaundler, is to determine the subarachnoid pressure. When this is taken in the erect sitting posture it varies between 20 and 25 millimeters of mercury in health, while in chronic hydrocephalus or tubercular meningitis it may run up to 40 millimeters and even much higher. The difference between the pressure in the erect and recumbent postures is nearly one-half, owing to the disappearance of the hydrostatic pressure when the child lies down. After death the pressure falls by more than one-half, on account of the cessation of the heart's action. In a dead child, in the recumbent posture, the slight remaining pressure (about two millimeters) is due to the elastic wall of the subarachnoid sac. The subarachnoid pressure is therefore complex, and decomposable into vascular or vital, hydrostatic, and elastic. These studies in manometry, while of much interest and significance, are not adapted for routine clinical work outside of hospital practice. With regard to the clearness of the fluid obtained by tapping, the admixture of decomposed blood implies the
presence of an antecedent trauma or pachymeningitis. If the fluid is clear, all inflammatory affections, aside from tubercular meningitis, may be readily excluded. In the latter disease the fluid is always clear at the outset and may even remain so throughout, but there is often present a peculiar cloudiness or opalescence. In the same affection the formation of a peculiar coagulum upon standing is almost pathognomonic. Much may be learned from a study of the sediment, as in meningeal disease of any sort abundant pus and blood-corpuscles and desquamated endothelia from the ependyma are present. Another almost certain indication of the presence of tubercular meningitis is the occurrence of a large amount of albumin in the fluid. The bacteriology of the sub-arachnoid fluid comprises the constant presence of the tubercle bacillus, pyogenic cocci, and Weisheilbaum's meningococcus in the corresponding disease, tubercular, supplicative, and epidemic cerebrospinal meningitis. With regard to therapy, the indications for puncture are to lower intracranial pressure and thereby remove symptoms due to pressure and irritation (headache, delirium, convulsions), and to drain away pathogenic bacteria and toxic products. There is no doubt that puncture has been successful in curing cases of epidemic cerebrospinal meningitis.

A FORMULA FOR SUBACUTE CONJUNCTIVITIS.

Ichthyol, 7 grains;
Oxide of zinc, 30 grains;
Lanolin,
Vaselin, of each 2 drachms.

Journal des Praticiens, May 13, 1899.

ON THE TREATMENT OF TUBERCULOSIS.

The Montreal Medical Journal for July, 1899, contains an article by Blackader in which he gives the following details as to the management of tubercular patients. In considering the subject of diet of these patients, it is only necessary to emphasize the importance of the maintenance of nutrition as a factor in the treatment; tuberculous patients with active disease require a much larger quantity of food than those in health, to compensate for the increased waste of tissue; and if digestion is unimpaired, they can usually assimilate well this increased amount. The food as supplied at ordinary meal hours should be plain, well cooked, and nourishing, but at the same time savory, and varied in character. In addition to the ordinary meals it is often desirable to furnish these patients with some liquid, easily digested food between meal hours; a cup of hot coffee or tea containing a large proportion of milk, given the first thing in the morning shortly after awaking, relieves cough, assists expectation, and at the same time counteracts the feeling of exhaustion which often follows the morning spell of coughing and distinctly interferes with the enjoyment of breakfast. At 11 A.M. a tumblerful of milk or beef tea, a cup of some nourishing but easily digested farinaceous food, taken warm, relieves the irritating cough, and tends to induce sleep. As an interne at Brompton Consumption Hospital, Dr. Blackader had frequent occasion to note the marked improvement in appetite and nutrition which followed the employment of simple stomach remedies, such as a mixture containing sodium bicarbonate with a simple bitter, or hydrochloric acid with nux vomica. He says he is not surprised, therefore, to note that Kingston, in a recent article in the Practitioner, and Fowler, in his late work on Diseases of the Lungs, both emphasize the value of such simple medication.

Alcohol in general is of value only so far as it favors the digestion and assimilation of food. In patients who rapidly increase in weight, and who show any tendency to increase of pulse tension, it may favor hemoptysis, and is therefore to be avoided. Cod-liver oil is our most rapidly absorbed and most easily assimilated fat; it is, therefore, a food as well as a medicine of acknowledged therapeutic value. The majority of tuberculous patients take cod-liver oil with advantage, and many authorities acknowledge that a patient will gain weight while taking cod-liver oil, although he fails to do so under other medicines. Should it impair appetite, give rise to acrid eructations, or increase diarrhea, it should at once be discontinued. Hydrotherapeutic measures are among the most valuable adjuvants in the treatment of the disease. Cold compresses are extremely serviceable for the relief of many of the minor ailments of tuberculous patients; while the cold sponge or douche, taken in a regular, methodical way, is of great value in toning the vasomotor system, and preventing the tendency to "catch cold" easily, so notable in many tuberculous patients. The best chest protector, says Ransome, consists in well douching
the chest night and morning with quite cold salt water.

In regard to special medication, there is no occasion to repeat what must be well known facts. In Dr. Blackader's opinion, every accessory means of improving general nutrition should be taken advantage of, while all nauseating or depressing drugs should either be altogether avoided, or used in the most sparing quantities. Strychnine, as a stomachic and general cardiac and respiratory stimulant, will in many cases prove of great service. Creosote in moderate doses is occasionally of much service in checking fermentation in the alimentary tract; it also appears to be of decided benefit in cases associated with much bronchial irritation or secretion. Stubbert has employed ichthyol in keratin-coated pills with much success, especially in patients suffering from intestinal complications. He states that in a number of patients treated with ichthyol in daily doses of from six to ten grains, the results on weight, expectoration, cough, and the disappearance of bacilli were ten per cent better than those obtained from the employment of creosote or any of its derivatives. Dr. Blackader's own experience with the drug has been too slight, he states, to draw any conclusions.

SOME ASPECTS OF CHRONIC MALARIAL INFECTIONS AND THEIR TREATMENT.

W. H. Thomson, in an article on this subject in the New York Medical Journal of July 15, 1899, tells us that it has been a matter of common experience, especially in the treatment of malarial fevers in the tropics, that the action of quinine appears to be promoted by the simultaneous administration of various spices. The remarkable farrago of compounds in Warburg's tincture, the original formula of which is said to have called for seventy-six ingredients, doubtless owes much of its efficacy in chronic malarial disorders to its predominant proportion of spices. Dr. Thomson, therefore, has been accustomed for many years to prescribe powdered ginger along with quinine, in equal quantities, and he has felt convinced that he could get along with smaller doses of the quinine itself by adding the ginger in the treatment of our ordinary intermittents. He says he has known ginger alone, administered in a large dose in hot milk, to break up chronicague of the quartan type when quinine had conspicuously failed. In a number of cases he has also added pulverized capsicum, a grain to four of quinine, and it is curious that the first dose of this combination often acts as a free purgative.

But cases of chronic and severe malarial infection are continually occurring in which quinine seems wholly to fail to cure the disease. Such a problem confronted him when his colleague at the Roosevelt Hospital, to whose service he succeeded on the 1st of September, told him that the soldiers in the wards had been there from the 17th of August, and that, though he had tried every form of administering quinine as to dose or method, as well as Warburg's tincture, and free administration of arsenic, yet the general results had been very unsatisfactory. In some cases large doses of quinine held the temperature for a few days, but only to be followed by relapses. The best results with this drug were in patients who had true intermissions, but these were a small minority, the fever with most of the others running a continuous but very irregular course, the predominant form of the plasmodium being of the estivo-autumnal variety. Dr. Thomson determined then to try the most ancient of known remedies against malarial poisoning—namely, opium—as an adjuvant to quinine. Forty-seven of the actively febrile cases, with temperature ranging from 103° to 106° F., were chosen, while check cases in equal number at first were left with the former treatment. He chose the camphorated tincture of opium as the most suitable preparation on account of its stimulant properties, and gave it in three daily doses of half an ounce each, with doses of fifteen grains each of quinine and of ginger twice a day.

As Dr. Thomson has already published a detailed account of his observations on the effects of the camphorated tincture of opium as an adjuvant to quinine in these Roosevelt Hospital cases, he quotes from it the following: "In twenty-two, or forty-seven per cent, of the number who took paregoric, the result was an immediate break in the fever—that is, the temperature fell to normal in twenty-four hours, nor did it rise again afterward. This effect was the more impressive because in every instance they had been unavailingly treated with quinine and Warburg's tincture for an average period of ten days previously without reducing the fever. Of the remaining twenty-five out of the forty-seven there were ten patients, or about twenty-one per cent, in whom it took from thirty-six to forty-eight hours to reduce the temperature
to normal. No relapse was recorded in the case of any patient who took paregoric treatment after the temperature was once reduced to normal."

Sir William Roberts, chairman of the British Royal Commission, appointed to investigate the opium question in India in the years 1893-94, maintains that the antimalarial properties of opium are due to its alkaloid, commonly named narcotine, but which he maintains should be termed anarcotine, as it has neither anodyne nor narcotic properties. The proportions of the two alkaloids in Smyrna opium are morphine eight per cent, narcotine two per cent; while in Bengal or India opium the proportion is morphine four per cent, and narcotine six per cent. In many cases, according to the voluminous statistics of British India surgeons, narcotine administered alone has been more efficacious than quinine as an antiperiodic. One of the most striking effects of the paregoric treatment in Dr. Thomson's hands was its unlooked-for antistuporous properties, so to speak. Instead of manifesting the usual symptoms of opiates, many of the actively febrile patients were roused by it out of the characteristic lethargy of the fever, and even in the weak apyretic patients with pronounced anemia the testimony was almost uniform that they felt better and stronger after taking it, the effects appearing the very reverse of narcotic and more like those of a cardiac and general nervous stimulant. He has noted analogous results also in private practice in the treatment of chronic malarial infection, notably when the patients complained of repeated headaches and general malaise, so that he has no hesitation in recommending this preparation of opium as one of the most trustworthy agents in the management of this common cause of prolonged invalidism in our climate.

THE TREATMENT OF SUMMER DIARRHEA IN INFANTS.

The Medical News of July 15, 1899, contains an article on this subject by Chapin which is apropos, in view of the articles published in the Gazette. Like all other writers on this topic he believes that in the dietetic treatment of summer diarrhea, as a majority of the cases consist largely of milk poisoning, all forms of milk must be temporarily withheld. Even the breast may be withdrawn in nursing babies until vomiting ceases. In the interval water may be frequently given, but in small quantities at a time, if the stomach tends to reject it. The common mistake is in giving too much nourishment at this time, as the infant seems to be weak and in need of support. It is not the food taken but that which is assimilated that supports, hence it is folly to force milk upon a baby at a time when the digestive powers are weakened, if not entirely arrested. Many a summer diarrhea would be stopped at the very beginning if milk were entirely withheld for from twelve to forty-eight hours.

When it is necessary to withhold milk for any length of time, other forms of nourishment may easily be substituted. One of the most easily procurable and satisfactory is egg-water. The white of an egg is thoroughly stirred in half a glass of cool water. This forms a pure and easily assimilable albumen-water. The only objection is its tastelessness, and Dr. Chapin has overcome this by the addition of about ten drops of aromatic spirits of ammonia. In case there is a tendency to vomit, this aromatic stimulant in small doses, as above, seems to check the stomach irritation.

Among other substitutes for milk may be mentioned thin gruels made from barley or wheat flour and cold whey. When the cereals are used, the starch may be easily dextrinized by one of the preparations of diastase that are now on the market. If cow's milk is withheld for several days or longer, mutton broth from which all the fat has been carefully skimmed makes a good substitute. Expressed beef juice with the fat removed and diluted with cool water makes a stimulating and nourishing drink.

When the acute symptoms have subsided and milk is resumed, it must be tentatively begun at long intervals and with high dilution. If a prescription to be filled at a laboratory were written it might call for fat, 1 per cent; sugar, 4 per cent; proteids, 0.50 per cent; or plain fresh milk may be diluted five or six times with sugar-water. By thus starting with a considerable reduction of the casein and fat, these solids may be gradually increased to a proportion that is proper for the infant's age and development. The difficulty of digesting the tough curd of cow's milk is a constant source of trouble. After trying various methods of overcoming this difficulty, a proper dilution of the milk with decoctions of the cereals as advised many years ago by Jacobi has yielded the best results in Dr. Chapin's hands. In hot weather a gruel made of wheat or barley flour, and
partially or completely dextrinized, will
modify and attenuate the clots of casein in
a favorable manner.

In a series of experiments recently made
through the courtesy and with the coopera-
tion of Prof. Graham Lusk at his laboratory
in the University Medical School, liquid
rennet was added to various preparations of
milk and heated to 40° C. Equal parts of
barley water and milk gave smaller and more
flocculent curds than equal parts of plain
water and milk. A dog with gastric fistula
was fed on consecutive days with these solu-
tions, and the contents of the stomach with-
drawn at the end of half an hour. The clots
were finer and apparently more digested
when the barley water and milk was used
than in the case of plain water and milk.
Aside from the results of such experiments,
the clinical effect of diluting with the gruels
must commend their use. Babies are less
apt to vomit tough, stringy curds, or to pass
them by the bowel.

The medicinal treatment usually assumes
less importance in direct proportion as the
preventive and dietetic management are care-
fully followed. Indiscriminate and abun-
dant drugging in this disease is now rele-
gated to the limbo of the past—astringents,
antiseptics, and opiates alike. The real indi-
cations for drugs are few and easily appre-
chended. As summer diarrhea is so apt to be
of a putrefactive nature, all agree upon the
necessity of completely clearing out the
gastrointestinal tract as a necessary start in
treatment. In most cases, when the physi-
cian is called, the stools are loose and there
may be vomiting. By at once stopping all
milk the stomach is soon emptied, and the
principal indication is to clear out the bowel.
If vomiting continues, drafts of tepid water
may be administered, which, when rejected
by the stomach, washes out that organ. Dr.
Chapin does not believe it is often necessary
to wash out the stomach with the tube.
Sometimes when there is excessive irritation
of the stomach, with much production of
mucus, one washing out, however, will give
relief. Dr. Chapin usually employs tablet
triturates of calomel, one-tenth of a grain
every hour, until six or eight have been
administered. These small doses act as a
sort of stimulant to the bowel, increase
glandular secretion, and usually effectively
clear the canal of its fermenting contents.
The drug is also supposed to have some
antifermendative effect. A good sized dose
of castor oil is also effectual, and is followed
by a sedative effect on the mucous mem-
brane. If the stomach is very irritable, it
may be difficult to administer on account of
vomiting. Elimination may sometimes be
hastened by irrigatipg of the lower bowel
with normal salt solution. Mucus as well as
fermenting milk may be thus removed. For
those not accustomed to this procedure, a
hard-rubber rectal tube is preferable, as the
soft tube bends on itself on account of the
length and marked curve of the sigmoid
flexure in infants.

The drug that Dr. Chapin has found most
useful in the summer diarrhea of infants is
the subnitrate of bismuth in large doses. As
far as he has observed the subcarbonate,
salicylate, and subgallate of bismuth and
betanaphthol bismuth have no decided ad-
vantage over the subnitrate, which is every-
where procurable. A baby of from six to
twelve months can take from ten to twenty
grains of the subnitrate every two or three
hours. The insoluble quality of the bismuth
and its sedative local effect make it most
valuable. Irritation and fermentation, even
under proper dietetic management, remain
longest in the ileum and colon, and this tract
is reached by the local action of the bismuth.
Most of the so called antiseptics have irritat-
ing qualities, and he does not think that even
in antiseptic action they act better than large
doses of bismuth.

It is manifestly impossible to put the in-
testinal tract in any condition that can be
called antiseptic by the administration of
drugs. Small doses of aromatic spirits of
ammonia, ten to twenty drops, well diluted
with water, seem to stimulate the mucous
membranes and refresh the infant. Dr. Chap-
in gives alcohol very sparingly in these
cases, as it seems to lower the digestive
powers. In case of great weakness or col-
lapse, from ten to thirty drops of whiskey
may be given well diluted. Formerly he
gave whiskey almost as a routine treatment
in these summer diarrheas, but now it is used
only for special indications and temporarily.
If the discharges are profuse and exhausting
and the baby sinks into a semistupor, with
depressed fontanel, very free stimulation by
whiskey and ammonia is indicated, as spuri-
ous hydrocephalus is thus ushered in.

There is one drug that was formerly much
abused, and is perhaps not used enough now in
proper cases, namely opium. It should never
be given combined with other drugs; indeed,
diarrhea mixtures of all kinds are to be de-
preciated. Opium is contraindicated until the
bowl has been thoroughly emptied of irritating contents, when the stools are scanty and foul-smelling, and when cerebral symptoms threaten. In cases, however, in which rapid peristalsis and profuse glandular secretion persist, a few moderate doses of opium are most valuable and may aid in saving life.

A CLINICAL STUDY OF TWENTY-FOUR CASES OF PARALYSIS AGITANS, WITH REMARKS ON THE TREATMENT OF THE DISEASE.

Collins and Muskens, in an article with this title printed in the New York Medical Journal of July 8, 1899, in discussing the treatment of this affection, state the well known fact that unfortunately no medication has yet been discovered that has any influence in shaping the course or changing the outcome of this disease. Beginners in the art of therapy should keep this in mind, and thus spare themselves the trouble of attempting a cure by any of the drugs—and their name is legion—that have been recommended during the last half century. Energy of this kind and zeal for experimentation may be legitimately expended, perhaps, in trials with new drugs and other health-restoring measures. But it should not be forgotten that one is not always justified in elevating the hopes of the patient for recovery so high or so often that when the promises are not fulfilled their confidence is so completely shattered that only harm results. Despite this depressing estimate of the value of drug medication in the treatment of paralysis agitans, much can be done to alleviate the symptoms, to prolong the patient's life, and to make him more comfortable. As in all other nervous diseases, the dietetic and disciplinary treatment are of the greatest importance. Their value is very conspicuously seen in patients who early in the course of the disease are obliged to seek the shelter of a hospital. Although they are apparently and really not very ill, as wage-earners they are incapacitated. The regular mode of life, and all that is implied by hospitalization, is conducive to avoidance of wear and tear, and such patients continue year after year without any material change except slight increase of rigidity, tremor, and the other cardinal symptoms. The first indication, then, is for the arrangement of an uneventful life, free from care, strife, excitement, and sordidness, in a congenial environment and healthful climate. As a rule, a cool climate is far more grateful to these patients than a hot one. Residence in the country or in the suburbs, where a maximum of fresh air, sunlight, and sleep are to be had, with a minimum of demand on the mind and the body, meets the requirements, providing the vital force of the patient is not put to a severe test in withstanding extremes of temperature.

The diet should be of a simple, nourishing, strengthening kind, and close attention must be given to the functions of digestion and of absorption, so that the bodily weight may be kept at the level which was normal in health. The comfort of the patient can be materially added to by regulation of the bowels and other eliminative avenues. It is absolutely necessary that the patient have the personal care of an attendant or of one of the family. Disastrous accidents have not infrequently followed neglect of this precaution. The customary measures for the maintenance of general muscular tone and nutrition, so serviceable in many functional and organic nervous diseases, such as the application of water and electricity, the use of massage and gymnastics, are not so appropriate in this disease as they are in many others. Nevertheless, lukewarm baths, of from twenty minutes to half an hour's duration, are often-times very soothing to the patient, and have a tendency to make the muscular rigidity less dominant. Moreover, they contribute to a moderate feeling of well-being, and assist toward the realization of refreshing rest, for which the patient generally clamors.

In patients under forty years of age, the application of water from 90° to 75° F. from the hand of an attendant, followed and accompanied by friction, is sometimes serviceable in combating the distressing attacks of local and general heat of which the patient complains. This measure can be utilized daily with patients who react well after it. Reaction may be facilitated by having the patient wrapped in a hot blanket previous to the ablation, by having him stand in hot water during the bath, and by light massage and external heat following it. Massage, applied as stroking and light kneading, fulfils practically the same purpose and is utilized for the same ends. It tends to lessen the spasticity, to improve the general nutrition, and to increase the patient's capacity for rest. Papotement or percussion should be avoided. Swedish gymnastics have been warmly recommended by some writers, but Collins and Muskens state they have never
seen anything but detriment attend their use. The same may be said of suspension, which has been plentifully tried, and of nerve-stretching. They are mentioned only to be advised against.

A few years ago Charcot promulgated the fact that many of his patients with paralysis agitans were more comfortable during and after a short ride in a jolting vehicle. Assuming that the jarring and vibrations had a soothing effect on the nerve centers from which arise the tremor and rigidity, this clinician had a chair so constructed that the patient or an attendant could, by pushing a pair of upright handles backward and forward, communicate vibration to the entire body. Such a chair was in use for many months in Dr. Collins’s clinic, but nowadays it subserves only a single purpose—a seat. Its usefulness is no greater than that of other vibratory apparatus, such as the one for the head, that have been constructed with a similar end in view.

Electricity has practically no place in the therapeutics of paralysis agitans, excepting so far as it is a potent agency for suggestion.

One of the most striking results of treatment in paralysis agitans is the temporary amelioration of all the symptoms on undertaking any new form of treatment. There is now under observation a man in the advanced stage of the disease who some years ago maintained that he was materially improved by some mechanical treatment given him by another physician. On inquiry, it was found that the “treatment” consisted of taking a few tracings of the tremor. Oppenheim states that he has seen considerable benefit follow the electric bath, and especially the application of the dipolar faradic current, but it is not improbable that the bath alone would have been accompanied by quite as much improvement.

The drugs that are in use for paralysis agitans, and from which some benefit in dissipating symptoms and fulfilling pointed indications may be expected, are hyoscynamus and dulloisine, Indian hemp, opium, hematogenous agencies, such as arsenic and iron, and occasionally gelasmum and veratrum viride. Of these, the most important by far are the two first mentioned. Given hypodermically, which is the preferable way when possible, or by the mouth, they promptly mitigate the severity of the tremor, and have a pronounced tendency to relax the muscular rigidity. They are both powerful toxic agencies, and must therefore be given with care. Hysoscamus (hyoscine hydrobromide, \( \text{H}
\) to \( \text{g}
\) of a grain) is said to have more advocates than dulloisine, but personally Collins and Muskens prefer the latter. Its administration is not so apt to be attended by disagreeable symptoms, while the effects are coequal. The sulphate of dulloisine should be given in from \( \text{H}
\) to \( \text{g}
\) of a grain, two or three times daily. On the accession of vertigo, cephalic paresthesia, disturbance of vision, nausea, dryness of the mouth and tongue, it should be stopped at once.

In many instances the administration of either of these drugs is followed by almost complete cessation of the tremor for a shorter or a longer time, but usually for several days. Unfortunately they apparently have slight effect in mitigating sleeplessness, amyosthenia, and the feeling of unrepose that so many patients complain of. When these become too burdensome for the patient to bear them unaided, opium or its alkaloids, preferably morphine, must be given, and especially to cause rest and sleep in advanced cases. Earlier in the disease reliance can be placed on the less baneful sleep-producers, such as sulphonial, trional, paraaldehyde, etc., given in the same way as they are for idiopathic insomnia. The salts of salicylic acid, particularly those of sodium and potassium, have been widely recommended, especially during the last ten years, probably suggested by the patient’s complaint of rheumatic pain and by the occurrence of other more characteristic phenomena of rheumatism. After thorough trial, Collins is convinced that such medication is quite useless. Considering the profound degree of depression in neuromuscular tone which patients with this disease have, it seems incredible that the bromides have ever been recommended or given, but unfortunately they have been. They are powerful agencies for harm, and the thought of their administration should never be harbored. In some instances, especially in those cases that are not benefited temporarily by dulloisine or hyoscynamus, some mitigation of the tremor and rigidity may be obtained by the administration of ge’semium or veratrum viride in from three- to five-drachm doses, three times a day. These drugs have served more satisfactorily as symptom medicines than Indian hemp, which has the recommendation of Gowers, and which has been widely used.
THE TREATMENT OF CHOREA.

The Archives of Pediatrics for August, 1899, editorially discusses how we should treat chorea. It believes that the mildest case of chorea should receive prompt treatment, not of necessity, however, by drugs. Rest is the most important factor in the treatment of the disease. The child, no matter how slight the movements may be, should be taken from school at once. He should be allowed to come in contact only with his own brothers and sisters, and with them only for limited periods during the day. He should be removed from all excitement, and all reference to his condition should be studiously avoided. Above all things, he should be removed from the possibility of ridicule or thoughtless reference to his misfortune. The parents should be particularly cautioned not to punish the child for any act resulting from weakness or from the choreic movements.

In mild forms of the disease absolute rest in bed may not be advisable. But even in that condition the child should be kept in bed each day longer than is his wont in health. In severe and increasing cases absolute rest in bed should be insisted upon. As the disease improves the child may be allowed to be up for two or three hours, the daily period being gradually lengthened. The diet must also be regulated very closely. Sachs is certainly very near the truth when he says: "Milk and rest will do more for most cases of chorea than any other two measures."

This treatment is most effective in the early stages, a time at which medication is least effective. It is entirely true that the rest treatment may be overdone, and judgment must be used, lest by its overcontinuance the monotony and lack of fresh air may counteract its benefits.

The question of exercise is one which demands sound judgment and must be decided largely upon the conditions present. When the disease is subsiding, exercise is certainly beneficial, but it should never be carried to the point of overfatigue, and exciting games of every kind should be proscribed. Upon the question of returning to school and resuming piano practice and more active games, it is wise to err upon the side of overcaution.

The tendency of chorea to recur should not be forgotten. Children who have once suffered from it should be watched for premonitory symptoms, it being remembered that the disease is far more common in the spring than at any other time of year. They should not be overcrowded in school, and should be particularly guarded against attacks of rheumatism.

The medicinal treatment of chorea is important, and when judiciously employed is of exceeding great value in controlling the disease, but the importance of combining with it the proper hygienic and dietetic management cannot be stated too positively. Differences of opinion regarding such treatment, it must be said, are less marked than in most other diseases. One drug is almost universally acknowledged to be of value—namely, arsenic. Its value in non-rheumatic cases is unquestionable. While its effects are not so pronounced in cases of rheumatic origin, its value even in them is usually great.

The dose of arsenic is frequently so small that no beneficial results are obtained. Beginning with three drops of Fowler's solution three times a day, it should be increased one or two drops a day until nausea or abdominal pain occurs or puffiness appears about the eyes. Treatment should then be stopped for twenty-four hours and then resumed, the dose being several drops below the highest previously given. The dose should again be gradually raised.

In many cases no improvement will be seen until slight constitutional effects are obtained. Unless distinct improvement is seen, the drug should be pushed to the point of tolerance. Twelve drops three times a day is usually the limit for a child of seven or eight years. Larger doses are frequently given, but they should be administered with the utmost caution. When these large doses have been reached, if no improvement is seen, other measures should be tried. Cases of multiple neuritis have been reported, resulting, it would seem, from excessive doses of arsenic. Its use in large doses demands the greatest caution and good judgment, and the patient while taking it should be kept under close observation.

Fowler's solution should never be given on an empty stomach. It should always be administered greatly diluted. It will thus produce very little gastric irritation. In prescribing the solution, it is wise to dilute it with one or two volumes of water, the dose being increased in equal proportion. Possible errors in measuring the dose thus become of less importance.

In rheumatic cases, particularly those in which acute rheumatism is present with the
chorea, salicylate of sodium is of great value. Under such conditions it is usually more efficacious than arsenic. It should be given in full doses, and the rheumatic symptoms should be brought under control as quickly as possible.

The use of antipyrin occasionally produces very brilliant results, and as often fails entirely. In our own experience it has proved most effective in nervous girls in whom the rheumatic tendency was slight. In cases which apparently result more or less directly from overwork at school or from neurotic conditions, it often proves very effective.

When the sleep is broken, trional is an excellent and very effective drug. In cases of great severity, where the violence of the movements and the interference with sleep threaten to consume the strength of the patient, bromide and chloral, or even codeine or some other preparation of opium, may be required; but such drugs should only be used in cases of extreme necessity.

Anemia is such a constant accompaniment of chorea that it should always receive attention. Some preparation of iron is, almost without exception indicated. The bitter wine of iron and syrup of the iodide of iron are particularly good preparations.

The natural history of chorea should not be forgotten in deciding upon the effects of treatment. After the third week the results of treatment are far more favorable than before that time, for the disease is then in its decreasing stage, or at least past the stage of increase. Failure to remember this fact accounts for many of the differences of opinion regarding the effect of drugs upon chorea.

**THYROID MEDICATION TO HASTEN THE UNION OF BROKEN BONES.**

There is perhaps some danger that, from having been contented for centuries with looking upon the thyroid gland as of no consequence, we may go to the opposite extreme of expecting it to accomplish things utterly beyond its power. In the *Écho Médical du Nord* of June 11, 1899, Dr. Lambret, chief of the surgical clinic of Lille and a railway surgeon, expatiates upon this proposition, and then comes down to the matter of the influence of the internal secretion of the gland on the osseous system. He is at some pains to recapitulate the leading observations on which we rest our present views of the part played by the thyroid in increasing the stature by its action, and of the relation of its defective action to dwarfing, rickets, cretinism, myxedema, etc. He recounts, in particular, that in 1895 Hanau and Steinle reported to a congress held in Frankfort their observations of the tardiness of the union of broken bones in animals that had been deprived of the thyroid gland, and suggested, as a corollary, the use of thyroid medication for promoting the formation of callus; also that in 1897 Gauthier recorded in the *Lyon Médical* his successful adoption of this hint in practice, a course which Quéné and Folet, too, found efficient, although the last named gentleman failed with it in one instance. There is good reason, then, to look upon thyroid medication as likely to prove of service in cases of delayed union of fractures.

But this is not all. There appears to be some ground, in the shape of a case reported by the author, for hoping that the same treatment may so hasten the union of broken bones as to shorten materially the time usually required for their repair, although he admits that no broad conclusions should be drawn from a single instance. The case was that of a man whose tibia and fibula were broken in a car-coupling accident. On the day after the injury he was put upon the use of capsules, each containing three grains of thyroid gland, three daily. On the seventeenth day union was found to be solid. All appliances were removed, and the man was allowed to get up. In these days of time-saving it is assuredly worth while to resort to Dr. Lambret's treatment in cases of fracture, and it ought not to take long to estimate its value.—*New York Medical Journal*, July 8, 1899.

**THE CHOICE OF DRUGS TO DILATE THE PUPIL.**

**JACKSON**, of Denver, who is well known for his work on refraction and retinoscopy, in writing in the *Medical News* of August 12, 1899, upon this theme points out that the influence of certain drugs in producing dilation of the pupil is so striking and so characteristic that they are mostly grouped under the name mydriatics. The most of these resemble each other closely in all their physiological actions and therapeutic capabilities. Yet several of them differ sufficiently in their influence to render the one or the other distinctly superior in certain cases; and one drug, cocaine, differs from the others so completely as to place it quite outside the group of true mydriatics, although it possesses a
power of dilating the pupil that is of the highest practical value. Along with their power of producing dilatation of the pupil (mydriasis), these drugs all possess in varying degree the equally useful power of causing paralysis of the ciliary muscle (cyclopia). In this paper their action as cyclopia will not be referred to except as cyclopia may be a valuable adjunct or a distinct disadvantage in their use as dilators of the pupil.

As the basis for choosing the particular drug most appropriate for a particular case, we have their somewhat different physiological actions on the pupil. Ten or twelve minutes after a drop of a solution of atropine 1 to 120 (four grains to the ounce) is placed in the conjunctival sac the pupil begins to dilate. The dilatation increases rapidly; the pupil at first reacts well to light, but is less and less affected by illumination as it grows larger. In fifteen or twenty minutes after it begins to dilate the maximum size of the pupil that can be produced by atropine is reached, and it becomes quite fixed, failing to respond to any of the forms of stimulation that produce reactions in the normal pupil. For about two days this condition remains unchanged. Then the pupil very slowly becomes smaller, and at the same time its reactions gradually return, until at ten or fifteen days after the application of the drug it has again become normal. Repeated instillations of such solutions prolong to any desired extent the period of complete dilatation, and recovery may be slower. Dr. Jackson says he has seen three full weeks elapse between the last instillation and complete recovery.

Reference is here made to complete recovery, the period of which can only be accurately determined when the drug is used in but one eye, the other being kept normal as a standard of comparison. Often in six or eight days recovery may be so far advanced that no great inconvenience is experienced from the remaining dilatation, and after that the recovery is so very gradual that some patients still think it not complete long after every trace of the action of the drug has passed away.

Dilatation of the pupil by atropine is accompanied by paralysis of the ciliary muscle and suspension of the power of accommodation. This begins with dilatation, reaches the maximum in one or two hours, remains complete for about two days, and then slowly passes off as the pupil contracts. With smaller doses of atropine the period of complete dilatation is shortened. A drop of a solution of 1 to 2000 does not produce complete dilatation and fixity of the pupil; and the return to normal will occur in eight or ten days. Of a solution of 1 to 500,000 a single small drop, containing less than one-millionth of a grain of atropine, will produce a perceptible enlargement of the pupil lasting from thirty-six to forty-eight hours.

The actions of the other natural mydriatics—daturine, duboisine, and scopoline— are almost identical, and closely resemble that of atropine. They are two or two and a half times as strong as atropine, so that used in solution of one-half or two fifths the strength they produce an equal effect. Recovery from their effects does not require so long as recovery from the effects of atropine. After complete dilatation by one of these drugs the pupil will return to normal in eight or ten days. They also cause complete paralysis of accommodation.

The artificial alkaloid homatropine differs essentially from any of the above in being much weaker in action, and in having a shorter period of recovery. A solution of 1 to 50 is required to produce complete dilatation and fixity of the pupil, and a single instillation of this does not produce complete paralysis of accommodation. Recovery is generally complete in two or three days. He has seen it complete in twenty-four hours, but in one reported case the period of its influence lasted longer than five days. Euphthalmine, an artificial alkaloid recently brought forward, is weaker than homatropine, and gives slightly greater dilatation of the pupils as compared with the diminution of accommodation that it produces. One instillation of a solution of 1 to 20 produces almost maximum dilatation, but not fixity of the pupil, and recovery is complete in about twenty-four hours.

In contrast with all the above is the action of cocaine; it never produces fixity of the pupil. After repeated instillations of strong solutions the pupil continues to contract, on exposure to strong light, and with convergence, yet even a single instillation of a solution of moderate strength will cause with feeble illumination a wider dilatation of the pupil than can be obtained by any application of atropine, or the stronger mydriatics. Dilatation produced by cocaine passes away in about twelve hours, and its effect on the accommodation is very slight. The superiority of cocaine is most marked in elderly persons, in whom the other mydri-
atics produce only imperfect dilatation of
the pupil. The influence of cocaine is well
shown by its effect in enlarging the pupil,
when fully dilated by one of the stronger
mydriatics.

Bearing in mind the special characteristics
of the different mydriatics, the author would
have us consider which will best meet the
needs of each particular condition, in which
the use of a mydriatic is indicated. To
dilate the pupil for ophthalmoscopic exami-
nation the indication is to dilate it quickly
and widely in the dark room for as short a
time as possible, and to cause the least incon-
venience and impairment of vision afterward.
This is particularly the case when there is
reason to suspect some progressive lesion
causing the impairment of central vision, as
albuminuric retinitis, or retrobulbar neuritis
with central scotoma. It has repeatedly hap-
pened that a patient suffering from one of
these diseases has been met in whom for
purposes of examination the pupil has been
dilated by one of the slower mydriatics. The
mydriatic caused immediate impairment of
vision, and by the time the mydriatic influ-
ence had imperceptibly passed away the
original disease had caused an impairment
of vision which replaced that produced by
the drug. It has usually been impossible to
convince such a patient that his eyes have
not been permanently damaged by the drops
that were put in them. On the other hand,
a mydriatic like cocaine, or a mixture of
cocaine and homatropine, causes compara-
tively little interference with vision at a:
y time, and its effect passes off so rapidly
that the patient realizes that he has recovered
from it before the more permanent loss of
vision by disease has progressed so far as to
be noticeable.

CYSTITIS IN WOMEN.

Shober contributes a paper bearing upon
this topic to the Journal of Medicine and
Science for August, 1899. He thinks that
the treatment of these various conditions is
quite simple and satisfactory if properly un-
derstood. The advice usually laid down in
the books is misleading and not sufficiently
positive. Dr. Shober says he wishes to em-
phasize very positively the opinion that some
form of local treatment is indicated in almost
all cases of cystitis occurring in women. Of
course, the old maxim to avoid local treat-
ment in the first stages of an acute cystitis is
to be considered, but even in these cases Dr.
Shober holds that if the symptoms do not
yield to the usual constitutional measures in
a very few days, one should not hesitate to
begin local treatment.

Much benefit and great relief will result
from a careful lavage of the bladder with
any one of the mild cleansing solutions.
The washing should be done under strict
antiseptic precautions, care being taken not
to overdistend the bladder. A very simple
apparatus for the purpose is used by him. A
pint jar with an opening at the bottom, hav-
ing a rubber tube attached and a two-way
catheter at the end of the tube, is filled with
the desired solution. This may be a decinor-
mal salt solution, or a solution of boracic acid
one drachm to one pint of water, or in cases
of gonorrheal cystitis, a solution of nitrate
of silver one-half to one or two grains to the
ounce. After the urine has been carefully
drawn, a small amount of the solution, one
to four ounces, is allowed to flow into the
bladder. This is drawn off or allowed to
flow off, and the process is repeated until
the water comes away clear. In this manner
an enormous amount of debris, shreds of
mucus, and exfoliated epithelium can be
washed out of the bladder. This proceeding,
depending upon the severity of the case, can
be carried out from one to three times a day.
The patient should be confined absolutely to
bed; the diet should be of the blandest kind
(if possible a milk diet should be insisted
upon), and large quantities of diluent drinks
should be prescribed. Other measures, de-
pending upon the cause, may be neces-
sary, but as a rule the above treatment will
be found efficient in most cases of acute
cystitis.

The majority of cases of cystitis in women
are of the subacute or chronic varieties. De-
pending as they do upon such a variety of
causes, these cases require many forms of local
treatment. By local treatment in this con-
nection Dr. Shober says he does not mean
direct application to the bladder walls, but
treatment directed towards correcting the
cause which has produced the cystitis. Uter-
ine deviations and misplacements must be
corrected, diseases of the ovaries and tubes
and pelvic adhesions must be overcome,
lacerations must be repaired, calculi re-
moved, etc.

In addition to lavage of the bladder, we
have another method of local treatment.
This is the treatment by direct applica-
tions to the bladder walls through the en-
doscope. It is especially valuable in those
cases where the disease is localized in one or more spots or areas in the bladder. The patient being placed in the knee-chest or in an elevated dorsal position, the endoscope is introduced, and the bladder, having previously been emptied, fills at once with air. Its entire surface can then be carefully inspected through the endoscope by means of the headlight. Spots of local inflammation can thus be treated by applications of much stronger solutions than can be used as a wash. Often one or two applications are sufficient for the cure of cases which have long resisted all other forms of treatment. The most satisfactory solutions for most cases, especially of gonorrhea, tuberculosis, and so-called solitary ulcer of the bladder, are the solutions of nitrate of silver from five to twenty grains to the ounce. Occasionally much stronger solutions may be used, if applied with skill and the greatest care.

As a last resort in those cases of cystitis which do not yield to the measures indicated above, we are justified in establishing a vesicovaginal fistula, to furnish an opening for the continuous flow of urine, and to put the bladder at rest.

The patient is allowed to be about, wearing a large pad of some absorbent material, to take up the urine. The pad should be constantly changed and the parts kept scrupulously clean. This is best accomplished by frequent washing and the use of thick zinc ointment. At the end of a few months the mucous membrane of the bladder is restored to a healthy condition, and the fistula may be closed.

THE CHOICE BETWEEN THE CÆSARIAN OPERATION AND ACCOUCHEMENT FORCÉ AFTER THE MOTHER'S DEATH.

The New York Medical Journal of August 5, 1899, speaking editorially of this matter, tells us that it is just possible that the advances that have been made in recent years in the technique of the Cæsarian operation, whereby it has almost been robbed of its fatality, have led to such a degree of readiness to resort to it in the case of the living woman, and a consequent utter lack of hesitation to perform it on the dead, as may prove disastrous under certain circumstances unless special precautions are taken. The danger was lately set forth somewhat graphically by Dr. Colle, at a meeting of the Société Centrale de Médecine du Nord (Echo Médical du Nord, June 25, 1899). Within a week of her expected confinement a woman fell dead, in his presence, with symptoms of pulmonary embolism. He went home hastily to obtain the instruments necessary for the Cæsarian operation. It was fifteen or sixteen minutes before he got back to the dead woman. Then he rapidly incised the abdominal wall and that of the uterus, tore open the fetal envelopes, and was fortunate enough to extract a child which, although cyanotic, soon began to breathe and was saved.

But an ugly rumor began its rounds; it was whispered that the doctor had killed the mother. This set M. Colle to thinking, and his reflections were not pleasant. He asked himself what material proof he should be able to offer that the woman had been actually dead at the time of the operation, in case he was accused; and prosecutions of physicians were so easily set on foot! At the meeting he mentioned these reflections and cited instances of women supposed to be dead who had regained consciousness during the Cæsarian operation. He was inclined, therefore, to prefer accouchement forcé in cases of the supposed death of the mother, for it could be performed at once, and the woman, if not really dead, be saved as well as the child, while the accoucheur's reputation was safe also.

M. Oui agreed with M. Colle that, after the mother's death, accouchement forcé was to be preferred to the Cæsarian operation, at least in private practice, for in the cutting operation the same precautions should be observed as if the mother were living, and that might really be the case. He cited Tarnier as having called attention to the very important consideration that it was always necessary to lose more or less time in obtaining the consent of the family to the performance of hysterotomy, whereas one could proceed at once to extraction per vias naturales and incur no reproach. M. Oui would use the forceps if he happened to have the instrument with him; otherwise there was but one resource—podalic version.

Perhaps the obstetrician of the present day may fairly be expected to go to a case of confinement prepared to perform the Cæsarian operation at short notice and with all the attention to detail that it requires, but certainly it cannot be required of him that he should be thus ready in the case of a woman who, being in apparent health, falls dead in his presence while he is making an
ordinary professional call on another member of the household, and is then ascertained to have been pregnant with a viable child—and this was M. Colle's experience. But the physician always has his hands with him, and can proceed instantly to dilate the cervix, rupture the membranes, turn by the feet, and extract—and that, too, without asking anybody's permission.

COTTONSEED OIL AS FOOD.

The Lancet of July 29, 1899, editorially considers this somewhat important subject in the following language:

"Because cottonseed oil has been employed by unscrupulous persons as an adulterant of olive oil and butter a certain amount of prejudice has been entertained against it as an element in dietetics. The case, however, with which cottonseed oil saponifies would indicate it to be a useful food and an excellent substitute for more familiar fats. Indeed, there is some evidence in favor of the view that properly refined cottonseed oil is as wholesome as butter. However wholesome and nutritious, though, cottonseed oil may be, it should be sold under its right name and should not be allowed to masquerade under titles to which it has not the slightest claim. The late Dr. Campbell Morfit devoted considerable attention to the purity of cottonseed oil for edible and pharmaceutical purposes. Some important observations connected with his researches in this direction have recently been communicated to us in a paper by his daughter. In this paper it is stated that the exceptional capacity for assimilation which cottonseed oil possesses when chemically pure can be demonstrated by five years' experience of its use in severe chronic dyspepsia. Where the diet was strictly limited and the stomach was intolerant of any other fat, even of butter, the daily consumption of a small quantity of cottonseed oil produced results unattainable, it is said, from any other food. Further, cottonseed oil is much less nauseating than cod-liver oil, while it is free from laxative tendencies, so that it may be exhibited, as in the case of tuberculous patients, where excessive waste has to be combated without overtaxing the digestive functions. It has been suggested as a suitable food for growing children and as a lubricant in massage treatment. It would appear, however, that cottonseed oil which has been refined by drastic bleaching agents loses many of its useful qualities. On the other hand, by employing such refining agents as will act upon the impurities solely, leaving the oil itself chemically untouched, a bright golden oil is obtained possessing a sweet, nutty flavor and evincing no liability to become rancid. Such an oil is well adapted for edible and culinary purposes, and since the output of the oil in many parts of the world is enormous, it is surprising that the claims of cottonseed oil as food have not previously been more widely made known."

SOME REMARKS ON THE PATHOLOGY AND TREATMENT OF GOUT.

Dr. Sydney A. Bontor, in an article bearing this heading published in Treatment of July 13, 1899, expresses the belief that the medicinal agents chiefly relied upon in the treatment of gout are colchicum, the salicylates, guaiacum, and the alkalies, with which piperazin, lysidine, and lithia may be included. There is no doubt that colchicum, although introduced into the treatment of gout by quacks, is of great value in relieving the pain of the acute attacks, but until recently no satisfactory explanation of its action had been found. Luff, however, has brought forward the suggestion that, by acting as a cholagogue, it prevents the glycocine from passing untransformed into the blood, and so acts directly as a preventive in the formation of uric acid; and in support of this he showed that administration of colchicum produced a diminution in the excretion of uric acid. Moreover, as its use is found by many to be beneficial in chronic as well as acute cases, this explanation seems a very reasonable interpretation of its mode of action.

The depressant action of colchicum upon the organs of circulation renders it necessary to observe a good deal of caution in asthenic cases.

Alkalies, especially salts of sodium, also have been almost universally used in the treatment of gout, especially in the acute attacks, because it was, and by some is still, supposed that the deposit of uric acid is dependent upon a diminished alkalinity of the blood. All writers who have especially studied the reaction of the blood—e. g., Rump (Centralb. f. Klin. Med., 1891) and Frenberg (Virchow's Archiv, Bd. 125)—have shown that its alkalinity is subject to very little variation, that mineral acids do not in the least affect it, and that organic acids in fairly large doses (acid. lact. 3 ii j to 3 v j, or
acid. tart. 3 j to 3 ij, daily) reduce it only by about one-sixth, and produce no further reduction; while Jacquet (Archiv f. Exp. Path., u. Pharm., 1892) was able to detect only a very slight diminution of alkalinity, even after the injection of acids into the veins of living animals. Notwithstanding this, the opinion is held by many that in gout there is a reduction of alkalinity, and that this increased acidity is the cause of the gouty deposit. Klemperer (Deutsche Med. Woch., xx, 1895) and Luff (Path. and Treat. of Gout, 1898) have shown that even in gout the reduction of alkalinity is very slight, and that in healthy individuals as great a reduction may also occur; while recent observations show that a greater reduction than takes place in gout occurs in such diseases as diabetes, acute rheumatism, etc., without any deposit of urate of sodium taking place. Moreover, Luff has quite recently demonstrated that the deposit of uric acid from serum does not take place until alkalinity has been reduced by at least fifty per cent by mineral acids, and seventy-five per cent by organic acids; and he points out that in order to produce such a diminution of the alkalinity of the blood it would be necessary to imbibe, all at once, two bottles of old port wine. But this is not sufficient either to indicate the use of port wine in the treatment of gout, or to contraindicate the use of alkalies, since the experiments relate only to uric acid; and we know that the deposit in gout occurs in the form of urate of soda, and not in the form of uric acid, although this point is frequently ignored in the consideration of this question. It is necessary, therefore, before we finally decide as to the suitability of alkalies in preventing the deposit of urate of soda, or dissolving it after it has been deposited, that we should ascertain the effect upon the solubility of this substance itself in serum whose alkalinity has been reduced.

The experiments reported by Sir Alfred Garrod seemed to indicate that some alkalies—the salts of lithia, potassium, and sodium—had some effect in increasing the solubility of biurate of sodium; but this observation was in opposition to that subsequently made by Sir William Roberts, and the recent investigations of Luff, carried out under conditions as nearly as possible representing those which would obtain if alkalies were introduced into the general circulation, support the conclusions formed by Sir W. Roberts, and are entirely opposed to the view of Sir Alfred Garrod. He found that neither potassium bicarbonate, potassium citrate, lithium carbonate, lithium citrate, sodium phosphate, piperazin, or lysidine, had any effect whatever upon the solubility of sodium biurate in serum, and that sodium bicarbonate actually reduced it to a certain extent. Moreover, by another series of experiments he showed that the conversion of sodium quadriurate into biurate is not at all delayed by an increased alkalinity of the blood; and therefore it may be assumed that the alkalinity of the blood has no effect upon the formation or the solubility of sodium biurate, and, consequently, that alkalies do not prevent the deposit of urate of sodium, nor do they sweep out any accumulation which may have occurred.

The objection to the alkaline treatment of gout was first raised by Sir William Roberts, and in support of his theoretical objection, based upon the experiments already referred to, he stated that “clinical experience on the use of alkalies speaks with doubtful voice;” but although their use does not receive universal approbation, it is nevertheless supported by a great weight of clinical experience, and with this we can fully agree. We have said that alkalies do not exert any influence upon the solubility of the uric acid in gout; but this is very far from saying that they have no value in the treatment of the disease. We have seen that the gouty uric acid formation is primarily due to defective metabolism of nitrogenous materials. Now, we know that some alkalies have a considerable influence upon metabolism and the improvement of the general nutrition, and consequently, by their remedial action upon the gastric and hepatic functions, they are able to bring about these good effects which have been attributed to them for so long; and therefore we may include in our prescription, some such salt as citrate of potash or citrate of lithia, not with a view to altering the alkalinity of the blood, but with a view to improving metabolism, and so of diminishing the production of uric acid, and to stimulation of the excretory action of the kidneys, whereby the elimination of the quadriurate may be promoted.

But while this argument applies to those of the alkalies, such as potassium and lithia, which act upon digestion, or have a marked diuretic effect, it does not do so to all—for example, the salts of soda. Sir William Roberts has shown that the solubility of biurate of sodium in water is practically 1 part in 1000, but if any salt of sodium be introduced, the
solubility is greatly reduced, and water containing only 0.7 per cent of sodium salt exerts practically no power of solution; and he, points out that all the sodium salts are alike in this respect, and also that the sodium salts present in serum reduce the solubility to 1 in 10,000, while serum from which the salts have been removed exerts the same solubility as simple water.

Luff has confirmed these observations, and therefore we may conclude that the introduction of sodium into the gouty system is to be avoided. Now, common table salt is a compound of sodium, and therefore Sir William Roberts has suggested that it should be excluded from the diet of the gouty; but to remove an article so important for flavoring purposes without providing an efficient substitute would be a serious matter, and he has suggested the use in its place of potassium chloride. In this connection Dr. Bontor says he may again draw attention to Dr. Luff's recently published experiments with the ashes of various vegetables, and his suggestions that a table salt should be prepared from this for use by the gouty in the place of the chloride of sodium now used. In view of the results which he has already mentioned, Dr. Luff suggests that a table salt might be prepared from the ashes of vegetables, and calculates that by the use of suitable vegetables and this table salt it would be quite possible to introduce into the body more than 0.1 per cent of mineral constituents of vegetables. The importance of this is at once apparent if figures are given for the solubility of sodium biurate: Plain water dissolves 1.1 per 1000; 0.1 per cent solution of common salt dissolves 0.45 per 1000; 0.1 per cent solution of spinach ash dissolves 1.90 per 1000. The salt solution thus has not half the solvent power of plain water, while the solution of spinach ash has four times the power of solution of common salt, and nearly twice that of water. The ashes of many other vegetables have also this increased power of solution.

Another series of drugs largely used in the treatment are the salicylates, but their use in gout, based upon their success in acute rheumatism, appears to be a mistake. It is true that a great increase in uric acid in the urine succeeds the exhibition of these drugs; but this increase of uric acid appears to be due not, as was originally supposed, to an increased elimination from the system, but to an increased production.

If this be so, then the use of salicylates, instead of being beneficial, would be harmful; and as the following evidence very clearly shows that it is an overproduction, and not an increased elimination, which is caused by salicylates, their use is distinctly opposed to our first object of treatment.

Careful examinations have shown that salicylates produce an increased elimination of uric acid in the urine in healthy subjects, and this increase must be due either to (1) an increased production, or (2) to a solution of gouty deposits. Now, all gouty deposits exist in the form of sodium biurate, but Luff has shown that solutions of salicylate in serum, in far larger quantities than could possibly exist in the blood, have no greater power of dissolving biurate of sodium than the serum itself; while, on the other hand, Boolland found that the administration of salicylates produced an increase of leucocytes. And if Horbaczewski's theory be correct, this would cause a considerable leucolysis, and as a result an increase of uric acid. Further, it is well known that salicylates unite freely with glycocine; and if our theory of the production of uric acid be correct, it is probable that this action of the salicylates is another cause of the increased uric acid excretion, since the glycocine carried to the kidneys by the salicylate unites with the kidneys to form the uric acid which appears in the urine. This increased production taking place with kidneys already incapable of eliminating their normal amount of uric acid would certainly tend to increase rather than allay the gouty condition.

Of guaiacum much difference of opinion appears to exist. It was originally introduced by Sir Alfred Garrod, and he states that he knows many hundreds of cases in which its use has been especially valuable. He advises its use for those cases where the gouty pains are relieved by warmth; and inasmuch as it is a stimulant to the liver metabolism, it is probable that his opinion of it as a powerful prophylactic is justified, and that guaiacum deserves a more permanent place among the remedies for gout than has hitherto been accorded it.

And, finally, as to the local treatment of gouty joints. During the acute attack, rest, elevation, and warmth are the essentials. The application of cold is most dangerous, on account of the frequency with which retrocedent attacks of vital organs may be induced; whilst the application of uric acid solvents is useless, since the deposit consists of biurate, and not of uric acid. During the
chronic stages hot baths, such as those of Bath and Buxton, will be of service, as also
the application of very hot, dry air. These act by increasing the circulation in the ves-
sels surrounding the affected joint, and so not only relieve the tension and pain, but also
promote the absorption of the deposit.

ON THE USE AND ABUSE OF NITRATE
OF SILVER IN THE TREATMENT
OF OPHTHALMIA OF THE
NEW-BORN.

HARRY FRIEDENWALD tells us in the Maryland Medical Journal of September 30, 1899,
that the treatment of ophthalmia neonatorum must be carried out properly—in strict ac-
cordance with Crédé's method. A two-per-
cent solution is to be used, and a single drop is
to be instilled directly upon the cornea as
soon as possible after birth. It will not do
either increase or decrease the strength of
the solution. Thus Howe's study has shown
that a one per cent solution reduces the per-
centage of ophthalmia only to 2.4 per cent,
or about four times that of the standard so-
lution.

The effect of stronger solutions and their
more abundant use may be very disastrous, as
is demonstrated by the following case: Last
year Dr. Friedenwald was called to see an
infant that had been born at 4 A.M. Soon
after birth several drops of a three-per-cent
solution was instilled, and in the early fore-
noon an attendant, believing that the treat-
ment had not been used; instilled some more.
The eyelids rapidly swollen, and when Dr.
Friedenwald saw the child there was a large
infiltrated area, embracing the lower half of
the cornea and presenting the typical picture
of a burn of the cornea. Under simple treat-
ment (boracic acid salve) the inflammation
subsided and the cornea cleared up to some
extent. This was evidently not a specific
ophthalmia; its onset, course, and appearance
proved it to be a burn from the nitrate of
silver.

In hospital practice no one questions the
propriety of applying Crédé's method; in
private practice it is rarely used. Is it not
almost criminal neglect not to use it when
the mother is known to have gonorrhea, or
even when this disease is suspected? The
conscientious physician who does not apply
it in cases of severe leucorrhoea, or when the
mother has previously borne children that
suffered with ophthalmia, will find it difficult
to relieve himself in his own mind from
blame if the infant he delivers develops
ophthalmia.

Now in regard to the curative treatment
of ophthalmia of the new-born with nitrate
of silver. Here it is equally important to
apply the remedy properly, but it is much
more difficult, for accurate judgment is re-
quired, and hard and fast rules cannot be
given. The solution is likewise usually two
per cent. In mild cases it may sometimes
be reduced to one per cent, and stronger
solutions are rarely required. The same effect
can be obtained with the two-per-cent solu-
tion as with the stronger solutions if it is
applied for a longer time.

It is equally important to know when not
to use the silver solution. During the first
stage of ophthalmia, when the lids are greatly
swollen, the conjunctiva is congested and
glistening and exuding a thin, straw colored
serum, with sometimes a fibrinous deposit
covering the conjunctiva; during this stage,
as von Graefe showed, the nitrate of silver
acts harmfully. If applied at all freely the
conjunctiva becomes covered with a dense
membrane which cannot be removed, and
which requires a number of days for its dis-
appearance. But what is most serious is that
this condition of the conjunctiva is frequently
followed by corneal ulceration. It is neces-
sary to curtail this state as much as possible,
and this can be done by means of cold appli-
cations; cloths which have been left lying on
a block of ice are placed upon the eye in
rapid succession and continuously, day and
night.

As soon as the serous exudate becomes
purulent we begin the use of the silver solu-
tion. But it is well to apply the solution
very gently at first, brushing it over the
conjunctiva but once or twice, for if applied
vigorously even now the false membrane may
make its appearance. The solution is not to
be dropped into the conjunctival sac as is
frequently done. The lids are to be thor-
oughly everted and the solution pencilled over
the entire surface. Many surgeons neutralize
the excess of the nitrate of silver solution
with a little salt water. Dr. Friedenwald has
been in the habit of taking up most of the
excess with a bit of absorbent cotton, and
he believes the small quantity remaining is
rather a benefit than a source of injury to
that part of the conjunctiva which cannot
be reached directly.

During the first few days, while there is
still much swelling of the lids, it is necessary
to continue the cold applications. It is most
important to keep the eyes free from collections of pus by frequently separating the lids and washing out the eye with some mild solution, such as boric acid solution.

The nitrate of silver is to be used once daily, and after the first application or two it is to be penciled over the conjunctiva until a thin milky layer is everywhere apparent; and it is well to follow this application with the cold cloths for half an hour or an hour to prevent too great reaction. This treatment is to be continued until the case is cured.

In that class of cases usually neglected in which a chronic ophthalmia is found, and in which the conjunctiva presents enormously enlarged papillae resembling the cock's comb—in these we are sometimes obliged to use stronger solutions, three or even four per cent, but with great care and careful protection of the cornea.

CHLORETONE: A NEW HYPNOTIC AND ANESTHETIC.

Houghton and Aldrich, who are doing such good pharmacological work, have contributed to the Journal of the American Medical Association of September 23, 1899, a statement concerning the use of this new and valuable drug. They tell us that during the past few months chlorozone has been quite extensively employed clinically. From their experience and that of numerous other observers they briefly outline its therapeutic properties as follows:

In cases of lacerated wounds, burns, etc., it is very efficacious in lessening pain when the injured parts are freely bathed in aqueous solutions of the drug. Owing to its antiseptic properties, it may be used independently as a surgical disinfectant, or if a strong antiseptic action is desired it can be employed in conjunction with mercuric chloride, carbolic acid, etc. Pain and uncontrollable vomiting of gastric origin may frequently be relieved by its internal administration. In one instance the drug proved especially useful in checking the persistent vomiting of gastric carcinoma. It may be possible that the drug will prove to be a useful therapeutic agent in preventing or controlling seasickness, vomiting of pregnancy, etc. Laboratory experiments quite conclusively show that it renders the mucous membrane of the alimentary canal insensible to irritants. Mustard, when given in an aqueous solution of chlorozone to dogs, fails to provoke emesis, the animal usually going quietly to sleep. That the mustard produces the usual amount of irritation is shown by the fact that if on the following day the animal is killed and the intestine examined, its walls are found much inflamed, the parts coming in contact with the mustard in some instances being nearly vesicated.

As a hypnotic, chlorozone is frequently efficacious in various conditions. Especially good results have been obtained from the exhibition of the drug in cases of persistent insomnia in the aged, and in cardiac disease with renal complications accompanied by high arterial tension. In many instances where morphine, chloral, trional, etc., have been unsatisfactory, chlorozone has been successful. Morphine, as is well known, increases the excitability of the nervous system when administered in large doses, and is frequently objectionable on this account. Chloral is quite irritating to the stomach and depresses the heart's action. Chloretone does not possess any of these disadvantages, being only rarely followed by disagreeable after-effects. Occasionally, when large hypnotic doses have been given, drowsiness occurs on the following day.

In general the authors summarize their claims for this drug by stating that its action on the central nervous system is similar to the anesthetics and hypnotics of the fatty acid series without depressing the centers of the medulla; locally, it acts like cocaine, as a peripheral anesthetic.

It is too early to prophesy what position chlorozone will take in medicine, but the results as a hypnotic and local anesthetic are very encouraging. As high as sixty grains has been given at one time without producing any untoward symptoms. From six to twenty grains given in tablets at a single dose, followed by a drink of water or milk, seems to be quite sufficient to produce the desired results. Possibly the drug will prove to be a useful general anesthetic when administered in large doses; or it may be given before chloroform or ether, and allow complete anesthesia to be produced by the use of a minimum amount of chloroform or ether. Perhaps such administration may prevent the annoying vomiting that so frequently occurs when a patient is being anesthetized.

DANGERS OF HEADACHE POWDERS, WITH TESTS FOR THE SUSPECTED INGREDIENTS.

The Medical Record of September 30, 1899, contains an article by Sobel upon this prac-
tical subject. He reports a case of poisoning and points out that its history presents a clear case of poisoning by headache powders, with the following symptoms: Marked cyanosis, prostration, cardiac weakness with irregular heart action, coldness of the extremities, dilated pupils, anxious facial appearance, but complete consciousness.

The next question was, what is the particular offending ingredient? Two drugs only occurred to Dr. Sobel's mind, viz., acetanilid and antipyrin. Phenacetine, on account of its expense, did not enter into the consideration. However, to surmise is one thing, to know another; accordingly he took samples of the powder to the Good Samaritan Dispensary, where, with Mr. F. C. Schumacher, he made the following tests: Each powder weighed ten grains, was of a brownish-white color, presented a shining appearance when rubbed on the fingers, and had a sharp, pungent, bitter taste. The appearance and taste were suggestive of acetanilid. When added to water the solution became flocculent, showing the presence of some insoluble substance, perhaps acetanilid, certainly not antipyrin, which is very soluble in water.

Tests for antipyrin: (1) To three grains of the powder ten cubic centimeters of water was added, and then five drops of tincture ferri chloridi; the solution became slightly colored. In the presence of antipyrin the solution would have turned a bright red. (2) To three grains of the powder ten cubic centimeters of water was added, and then two cubic centimeters of pure spiritus ætheris nitroso; the solution remained clear. In the presence of antipyrin the solution would have turned dark green, owing to the formation of isonitroso antipyrin. In making this test he emphasizes the use of pure nitrous ether, because otherwise even in the presence of antipyrin the test will fail. This test then is of double value, first in testing the presence of antipyrin, and secondly, the purity of the nitre.

Antipyrin having been excluded, acetanilid was tested for as follows: (1) Two grains of the powder was heated with one cubic centimeter of a concentrated solution of NaOH and three drops of chloroform added; an offensive, poisonous odor of phenylisocyanid \( C_6H_2NC \) was given off. This is the isonitril test and reacts to acetanilid. On the addition of bromine water the mixture became yellow-red, thus corroborating the presence of acetanilid. (2) Two grains of powder was heated to boiling with two cubic centimeters of hydrochloric acid, and an equal volume of a saturated watery solution of chlorinated lime added; this gave a turbid red or violet fluid, which turned dark blue on supersaturation with \( NH_2OH \) in excess. This is the indo-phenol reaction and speaks for acetanilid. (3) To two grains of the powder one cubic centimeter of a sulphuric and chromic acid reagent (chromic acid gr. \( \frac{3}{2} \), 10 Cc. of water, gr. xxx of concentrated sulphuric acid) was added; this gave an intense red color, which immediately turned blue and then faded. This test responds accurately to acetanilid.

Phenacetine was excluded by Mr. Schumacher with the zinc powder and tincture of chloride of iron test.

Thus, whatever other ingredients these powders might have contained, Dr. Sobel felt convinced that acetanilid was the disturbing factor and gave rise to the symptoms enumerated. It might be argued that in this instance the prostration and other symptoms were due to an overdose of the powders, and that had the original directions been followed nothing unusual would have occurred. It is, however, this very self-medication, this treatment without regard to idiosyncrasy or the underlying conditions, that is objected to.

All pharmacists under the existing laws have a perfect right to sell headache powders, proprietary or otherwise. It is highly advisable, however, that they prepare their own powders, know exactly how much of each ingredient they contain, and fortify them (if necessary) with cardiac stimulants such as caffeine, sparteine, monobromate of camphor, etc. No more than three grains of acetanilid should be dispensed in any one powder.

The indiscriminate self-administration of headache remedies composed of powerful aniline synthetics cannot, however, but work infinite harm, unless the public be warned against the great danger which lurks in this method of medication.

**THE PNEUMONIA QUESTION.**

Under this attractive heading Wells discusses this important question in the *Journal of the American Medical Association* of August 19, 1899. He believes that in pneumonia the treatment should resolve itself into reasonable prophylaxis; in making the patient comfortable; in preventing excessive formation of toxins, in neutralizing them, in encouraging...
their elimination and increasing the resisting powers of the system against their action; in preventing, or managing properly, the complications which may arise. Dr. Wells regrets that space will allow him to consider, cursorily, only a few of the many interesting and important questions here presented.

Bleeding in pneumonia has been discussed for so many generations and from points of view so diverse that he approaches the subject with reluctance, and it is only because he believes it a remedial resource which has no efficient substitute that he desires it to be considered at this time. It is not desirable that the former routine treatment of pneumonia by excessive bleedings should ever be restored to professional favor, yet Dr. Wells says he is sure that the physician who wholly abstains from venesection deprives his patient of a most potent remedy.

Venesection is not necessary in every case of pneumonia, and the patient, time, and conditions should be carefully selected. The very young and the very old, the weak and the anemic, should not, as a rule, be bled; nor those in whom evidence of obstruction of the pulmonary circulation, or of increasing toxemia, is not marked, but in others in whom these conditions exist the lancet should not be spared.

With an obstructed pulmonary circulation, there is a damming back of the blood into the right cavities of the heart and general venous system. The pulse is not rapid and has considerable tension; the breathing is oppressed, accelerated, and laborious; the patient is alarmed, and his anxiety is depicted in his countenance. This condition is usually met with only early and in plethoric and robust patients. In Dr. Wells's experience the relief afforded in such cases has been immediate and remarkable. Should the patient have passed into a dull or comatose condition with the first brunt of the attack, imminent danger is clearly present. Here successful treatment depends upon ridding the system as speedily as possible of the poisonous matters circulating in the blood and overwhelming the central nervous system, and free bleeding is the remedy par excellence.

In another and much larger class of cases the patient successfully withstands the first onslaught of the disease, but after a few days shows the indubitable signs of a profound toxemia, in a pulse which gradually increases in frequency while it loses in sustained force, in a high temperature, in restlessness and delirium, in sallowness or duski-ness of the surface; and these cases demand not only venesection, but a cleansing of the blood as well. If blood is simply abstracted from the general circulation, the serum is quickly replaced by the absorption of fluids from the soft tissues. At this stage of the disease, however, these fluids are loaded with toxins and leucocytes, and bleeding alone may fail in its object as a blood-purifier.

But if in addition to venesection there is introduced into the circulation a bland and non-toxic fluid, equivalent in quantity to that withdrawn, we not only remove a great and oppressive quantity of offending material, but we dilute that which remains behind.

The method of procedure is of importance. Dr. Wells's own practice is as follows: Venesection, to the extent of removing from four to sixteen or twenty ounces of blood, is done. If the symptoms of intoxication are profound, or if it is clearly evident that the patient will, and does, bear well the loss of blood, the bleeding should be a free one. If, on the contrary, opposite conditions prevail, the amount of blood withdrawn should be small. Indeed, in some of these cases, with profuse perspiration, free excretion of urine, or perhaps diarrhea, bleeding may be omitted.

Simultaneously with the venesection, or immediately before or after, a solution, in distilled water, of chloride of sodium .7 per cent, chloride of potassium .23 per cent, and chloride of calcium .03 per cent, is injected, subcutaneously, in quantity approximating that of the blood withdrawn. Often four or six ounces may be injected later, and repeated at intervals, according to the effects produced. The injections are multiple and are made with a large-bore needle, preferably by gravity, into the subcutaneous tissues of the chest. The fluid is warmed, and ordinary precautions are taken. In some cases high enemata of the saline solution may be substituted for the subcutaneous injections, and, when well borne and retained, with equally good results.

If this method is followed as detailed it is quite free from danger. Dr. Wells has employed it in a number of cases and has seen absolutely no undesirable results — no chill, no rapid rise nor profound fall of temperature, no restlessness nor excitement, no collapse. On the contrary, there has usually followed a gentle or profuse, but warm, perspiration, a free action of the kidneys, a clearing of the intellect and an abatement of cerebral excitement, a lessening of dyspnea, and an improvement of the circulation.
Such has been Dr. Wells's experience when these measures have been resorted to in the early stages of the late toxemia; but if they have been delayed until evidences of approaching death were manifest, the effects have been negative. In the one case the results of treatment have been satisfactory, and a fair proportion of patients have recovered; in the other they have, with this as under every other plan of management with which he is acquainted, uniformly died.

From first to last in pneumonia the vasomotor system, as reflected in the state of the capillaries, must be given assiduous attention. Failure in this direction, with capillary paresis, should be anticipated and met with efficient doses of digitalis and strychnine, and an occasional carefully gauged dose of morphine.

In conclusion Dr. Wells says that in spite of the fact that the ordinary management of this affection in times past—recent as well as remote—has been, on the whole, signal unsatisfactory, and that that in vogue to-day is scarcely a promise of the advances of tomorrow, he believes that the immediate future will demonstrate pneumonia to be certainly a preventable and largely a curable disease, and that in this field the morning light of the twentieth century will see every reasonable hope of medical optimism abundantly realized.

**THE TREATMENT OF PLEURITIC EFFUSION IN CHILDHOOD.**

The British Medical Journal of August 19, 1899, contains a paper by Maguire upon this subject, in the course of which he says that having determined that an effusion is serous and not purulent, we must deal with the question of how it must be treated in a child. Positive tension in the thorax is a very important guide, though, as Dr. Maguire states, it rarely occurs in children provided that the effusion is simply serous. It is detected and estimated by bulging of the intercostal spaces and by depression of the diaphragm and its underlying viscera. But displacement of the heart is no evidence of its presence. The heart can be displaced by even a small pleural effusion, and we must not be misled by this, nor deceived into thinking that because, as it is still often expressed, "the heart is pushed to the opposite side," there must be immediate operative interference. The heart is scarcely ever "pushed;" it is simply drawn by the retraction of the opposite lung and of the mediastinum.

But depression of the liver, stomach, and spleen is a different matter; and further, such depression is generally accompanied, even in children, by engorgement of the cervical veins and great dyspnea. Then, undoubtedly, aspiration is the best treatment, and must be pursued, whether the fluid withdrawn be blood-stained or not. Dr. Maguire says that in the preliminary puncture the aspirator, and not the ordinary needle, should be used. If there be no such signs of positive tension as he has described, and the fluid withdrawn is deeply blood-stained, he thinks it is better to stop the aspiration at once. To pursue it would only draw more blood to the inflamed lung, which probably underlies the effusion. Suppose that the effusion be only moderate in amount, that there be no signs of positive tension, and that the fluid be not unduly blood-stained—the usual conditions under which such effusions are met with—here, again, he says that aspiration is best not proceeded with. For once purely medical measures are the best. Dr. Maguire is no advocate for any attempts to draw off the fluid by artificial channels—as, for instance, the kidneys—say by the aid of diuretics. There is no need for any such course. Moreover, the resistance of the child's lung is so great that, even after a long collapse, it will expand normally, thus differing from the lung of the adult. But this depends greatly upon the maintenance of the general health.

Fortunately, in children tuberculosis is rarely the cause of pleuritic serous effusion. Sir William Jenner stated that it was the frequent cause of empyema, and recently Netter has denied this on the ground of bacteriological examination. But Netter has also trusted simply to microscopic examination, and has not applied the test of inoculation to the fluid obtained from his cases; therefore his results are by no means reliable, and in the case of purulent effusions Sir William Jenner's dictum must be considered unshaken, supported as it must be by the clinical experience of all. This, however, refers only to purulent effusions. With regard to serous effusions, one may safely hold the opinion that tuberculosis is rarely present in such cases as they occur in children. Yet there occur cases of serous pleuritic effusions in which there is undoubted evidence of the presence of tubercle in the lungs, and in such cases he strongly advises non-interference with the effusion. The
same rule applies to adults also, and he hesitates to give a conjecture as to its rationale; he says he will merely state what has been supposed. It has been thought that the relief of the lung from the presence of the effusion may lead to increased circulation through the lung, and therefore to increased activity of tuberculous inflammation. This seems a very improbable view for many reasons, which need not be discussed here.

Another idea is that in the effusion from a tuberculous lung there may be an antitoxin, the result of the cultivation of the bacillus on human soil, and that the gradual absorption of such antitoxin prevents the further development of the tuberculous process. For this view we have no proof, but the theory seems well worthy of further investigation. Let us at present be content with the fact, of which Dr. Maguire says he is well satisfied, that it is better to leave tuberculous effusions alone, provided that they do not produce signs of positive tension amounting to pressure, which would endanger the functions of the other thoracic viscera.

Next we must think of the treatment of such simple inflammatory but non-tuberculous effusions as we have determined to not warrant aspiration. To maintain the general good health by good feeding and hygiene is the great point, but the disappearance of the fluid may be hastened by the administration of gray powder. This is exceedingly old-fashioned treatment, and was much cried down by Sir William Jenner. Nevertheless, Dr. Maguire is of the opinion that our forefathers were right in its use, though possibly they carried it to excess. Judiciously employed, he has seen it act powerfully as a remedial agent, and with no bad effects. He sees no reason to insist upon absolute rest for the young patient who has a pleuritic effusion, provided that the inflammatory process has subsided, and that there be no signs of positive tension in the thorax. Judicious open-air exercise is sometimes of great use in removing such effusions, and probably acts by increasing the general nutrition. Naturally the same advice cannot be given to adults, for in them there is a greater risk of heart failure.

So far Dr. Maguire has only mentioned simple serous effusions. But if our initial puncture—or aspiration, as he recommends—should show the presence of pus, what, then, should be our procedure? He would advise that in the first place we should try to find the source of the infective material, and still further to take warning from the presence of the pus to prevent its formation in other cases. He says he wishes here to give a special word of warning. On no account would he decry the operation for the removal of adenoid growths of the nasopharynx. There can be no doubt in the minds of any of us as to the need of such operation at times for the mental as well as physical well-being of the patient. In regard to the operation, he finds fault with the surgeons mainly, and almost wholly, because they are not sufficiently thorough in their removal of such growths, and fail to clear the parts of the pharynx which lie near the base of the skull, and which therefore interfere with mental development. But more judgment is required in choosing the time for such operation, and more precautions are necessary to insure asepsis. There can scarcely be conceived a surface more capable of septic infection than the newly scraped lymphatic tissue left after such an operation. Recently Dr. Maguire was called in to see a case where he prevented such an operation, proposed to be performed actually at the time when the patient was suffering from suppurative inflammation of the middle ear. How could the young patient under such circumstances fail to develop a highly septic wound? He says he mentions the matter here because empyema sometimes occurs as one of the septic manifestations—and by no means the most serious of them—caused by this operation.

Cases will arise at times in which the ordinary and best operation for empyema—incision—cannot be performed. For instance, the patient's friends may object to operation; and again, empyema may present itself on both sides of the chest, and it is almost impossible to open both sides and disable both lungs. What are then the dangers which may attend leaving the empyema alone, and also those which may result from treating the empyema by repeated aspiration? There is no doubt that empyema will sometimes, but rarely, get well by resorption and with no accidents. In the child, too, perforation of the abscess into the lung is not common, and perforation through the chest wall is still rarer. The great danger, then, is that of septic infection, causing acute inflammation elsewhere, or gradual interference with the body health, and marasmus, with death from asthenia. Some of these dangers, however, can be avoided by repeated aspiration, and the patient thereby restored to health. As an in-
stance of this Dr. Maguire mentions two cases: one was a child whom he saw in consultation with Dr. Reid, of Lambeth. The parents objected to operation, so Dr. Reid aspirated three times, drawing off about thirty ounces of pus on each occasion, and the child quite recovered. Again, he has a child under his care at the Brompton Hospital in whom he diagnosed empyema, and asked Mr. Godlee to operate, but before he could do so an empyema developed on the opposite side. One empyema was incised, the other being treated by aspiration, and the child is doing well.

Two other conditions of pleural effusion Dr. Maguire mentions briefly to complete the materials for discussion from the medical standpoint; these are effusion, generally purulent, encysted between the lobes of the lung, and effusion, purulent or serous, as it accompanies pneumothorax.

Effusion between the lobes of the lung is more common on the right side, because here there are three lobes instead of two, and its diagnosis, by no means an easy matter, is of great importance for treatment. Such an effusion shows itself mostly by mere simple pleuritic signs limited to a spot near one of the interlobar fissures, and with only very obscure signs of fluid effusion. Exploratory puncture is very uncertain in its results, for, as he has not infrequently seen, there is only one limited area through which the needle can reach the fluid. Yet it is always desirable to get at the fluid, whether serous or purulent, before it bursts into either the general pleural cavity or a bronchus. The knowledge that such a condition may be present, coupled with the finding of the limited pleurisy described, and possibly the absence of pneumonic signs, will often lead to its detection. In such cases there is rarely any displacement of the heart, for the locality of the effusion tends to prevent it interfering with the dynamics of the chest. Diagnosis here is everything, for treatment must be pursued according to the usual rules.

Finally, Dr. Maguire mentions the effusion which accompanies pneumothorax. Commonly this is purulent, but sometimes serous. He says he will not go further into the question of its mechanism than to refer to a very curious thing. By reason of the generally prevailing negative tension in the thorax, pleural effusions are usually removed from the influence of the force of gravity. So far as he knows, this is the only instance in nature where such a thing occurs, but when air obtains access to the pleural cavity matters are very different. An ordinary effusion does not obey hydrostatic laws when the position of the patient is changed. An effusion with pneumothorax behaves just as any other fluid would do, and this no matter what the character of the effusion may be, though naturally the thinner the effusion the more mobile it will be.

Dr. Maguire says he cannot too strongly impress the importance of thinking over and understanding these curious conditions of dynamics as they exist in the thorax. Such a consideration led to the invention of the aspirator by a physician, and physicians may reasonably expect to be allowed to use that instrument.

Dr. Maguire says that pus is best removed from the thorax. But he makes a little exception in the case of a small effusion of pus, and a fortiori one of serum, accompanying pneumothorax. Pneumothorax with or without effusion may well be left alone if its tension is not very high. Pus in the body is bad, but in the condition to which he refers he thinks the operation for its removal is worse. Pneumothorax is not a common condition in children, and he imagines none of us can report many cases from personal experience. But in adults he had an exceptional experience recently, for five cases of pneumothorax were at the same time present in his male gallery at the Brompton Hospital, and all with more or less effusion. As regards the effusion and the pneumothorax, all the cases were due to tuberculosis, yet four of the patients became quite well for all practical purposes, while one, having recovered from his pneumothorax, is now dying from coexistent tuberculosis. Not one of these patients was treated surgically.

**INTESTINAL ANTISEPTICS.**

BURNLEY YEo, in the Medical Press and Circular of August 30, 1899, in considering this theme, points out that intestinal antiseptics and evacuants have for a long time been in use without the rationale for their use being known. The old blue pill, together with the black draught which dissipated the "spleen" and the "vapours" for our forefathers, are instances to the point. Dr. Yeo considers the subject under four headings: (1) What is the scope of antiseptics? (2) What is the scientific basis for their use? (3) Under what conditions are they applicable? (4)
What are the means of applying intestinal antiseptics?

With regard to the first question, the medical use of antiseptics is different from the surgical use. The surgeon nowadays aims rather at asepsis than at antisepsis. But in medicine, as concerned with the intestinal contents, asepsis is impossible. We must if possible prevent, or at any rate antagonize, autointoxication—i.e., intoxication of the organism with the products of digestion.

With regard to the second question, it must be remembered that certain bacilli are only harmful in the presence of putrefaction or other abnormal condition. The bacillus coli, for instance, is a normal inhabitant of the intestine, and under ordinary circumstances is harmless. If, however, the bowel becomes abnormal in any way owing to catarrh, long-continued constipation, or sometimes injury, the bacillus coli seems to take on a virulent action. When associated with the bacillus typhosus it has the power to intensify the virulence of the latter. The experiments of Dieulafoy with the bacillus coli when taken from an appendix, the cavity of which had become shut off from the rest of the bowel, and the same organism when taken from the normal mucous membrane of the bowel, show that the former is virulent, the latter not so. As, then, the virulence of intestinal bacteria depends upon their environment, so by modifying that environment it is reasonable to suppose that we can modify their virulence.

In considering the third question Dr. Yeo says that intestinal antiseptics are indicated in gastric catarrh and fermentative dyspepsia. Grangé recommends in cases of summer diarrhea the use of plain boiled and cooled water. He claims that the use of this dilutes the toxins. There are many other conditions to which fermentative dyspepsia and autointoxication give rise. Such are dyspepsia, chest pain simulating angina pectoris, vertigo, aphasia, and anemia. Even pernicious anemia had been considered by some observers to depend upon some toxin which exerted a hemolytic action. There are three other diseases in which the use of intestinal antiseptics is rational—namely, cholera, dysentery, and typhoid fever. Of the first two Dr. Yeo has had no practical experience, but with regard to typhoid fever he has for some years advocated and practiced the use of intestinal antiseptics. Typhoid fever often exhibits symptoms of being due to a mixed infection, and this may explain the extraordinary variations in the severity of cases. He says he recalls instances in which the use of a chlorine and quinine mixture given every two or three hours has been attended with most marked results for the better in cases of typhoid fever. So, also, in some cases of indefinite febrile affections accompanied by rise of temperature, furred tongue, and foul-smelling stools, the use of thymol by the mouth, together with irrigation of the large bowel by eucalyptol, olive oil, and soap and water administered in the knee-sheet position, had rendered the patients well. Dr. Yeo says he is not able to say to what exact disease this condition was due, but he thinks that whether the original infection had been by typhoid fever or influenza, the condition which he was called upon to treat was due to the action of the bacillus coli in an abnormal environment.

With regard to the fourth question, the various intestinal antiseptics are: water boiled and cooled, calomel and salines, both of great value in the early stages of typhoid fever. Salicylate of bismuth and carbolic acid are both useful. As to the latter, Dr. Yeo says he remembers a case published recently in The Lancet by Dr. G. Williams, where a patient suffering from typhoid fever took by mistake one ounce of carbolic acid. He had, of course, to be treated for the toxic effects, but recovered from them with his typhoid fever symptoms much lessened. Salol is very uncertain. Eucalyptol and thymol are both good, and irrigation of the large bowel in such cases as have been mentioned is a necessity. Patients, especially in typhoid fever, must not be overfed.

Dr. Yeo concludes with a warning against the production of the modern manufacturing chemist who sets up to teach the clinical physician.

ETHYL BROMIDE AS AN ANESTHETIC IN MINOR SURGERY.

The Maryland Medical Journal of September 2, 1899, contains an article by Kempter upon bromide of ethyl. As regards its mode of administration, Dr. Kempter says he follows the plan of Dr. Chisolm. He uses a crash towel, folded in the shape of an airtight cone, rendering it impervious by a layer of paper, the base of the cone being sufficiently wide to cover both nose and mouth. He pours the full dose required to produce anesthesia into the inhaler, the dose in children ranging from one to two and one-half drachms, and in adults from two to three
drachms. He immediately covers the patient's nose and mouth, having previously instructed the patient to breathe deeply.

Having once applied the inhaler, he holds it down firmly, removing it only from the face when full anesthesia has been induced, which is recognized by the stopping of all struggling on the part of the patient. The patient may feel himself stifled; there need be no fear of causing asphyxia. Children struggle to escape from the inhaler; the cone, however, must not be removed for one instant from the face until full anesthesia has been produced. Should children cry it favors deep inspirations, which will assist in the anesthesia. Some hold their breath, but there is no danger that they will not "catch it" in time.

To the uninitiated it appears that the patient is being asphyxiated, and it impresses them as rather a barbarous procedure to keep the inhaler over a sometimes violently struggling patient. The cone must not be removed, for in no other way can rapid and safe anesthesia be obtained by ethyl bromide.

The time required to induce complete anesthesia depends upon the number and depth of inspirations taken. Generally speaking, one minute will induce deep narcosis.

Nausea or vomiting is of rare occurrence during its administration or at the period of deep anesthesia, which usually lasts about one and one-half minutes, rarely longer than two minutes. In most cases neither heart-beat nor pulse is influenced by ethyl bromide anesthesia.

The increase in pulse frequently is due to anxiety and fear and to the struggling of the patient, but after narcosis sets in it reaches its normal beat. The corneal reflex is present, with primary dilatation of pupil; the healthy color of the lips and skin is usually retained.

The patient awakes suddenly as if from a natural sleep, without loss of coordination and with a perfectly clear brain.

Dyspnea, short respiratory movement, and respiratory pause are unusual complications. Some after-effects, such as headache, somnolence, and amaurosis, have been noted.

Witzel, a German investigator, in 465 cases of ethyl bromide anesthesia mentions the occurrence of profuse perspiration in four cases and strangury in three cases.

The death-rate by the use of ethyl bromide as compared with chloroform and ether is summed up by a series of reports made at the Surgical Congress convening annually at Berlin. These reports cover a period of seven years, from 1890 to 1897, the mortality rate being summed up as follows: Chloroform, 2023 cases, one death; ether, 5090 cases, one death; ethyl bromide, 5228 cases, one death.

Reich, a German authority, estimates sixteen deaths in 60,000 cases of ethyl bromide anesthesia. These figures are given in Dr. Ernst Hankel's Handbook of Artificial Anesthesia, Leipzig, 1898.

If we do not permit ourselves to be intimidated by the pessimistic accounts that one reads in the average textbook about ethyl bromide, and follow certain practical rules, danger from this form of anesthesia need not be feared.

The adult dose should not exceed three drachms. Owing to its volatile properties and liability to decomposition, the inhaler should be applied immediately and retained to the patient's nose and mouth till full anesthesia has been induced. Under no circumstances should the inhaler be removed for the purpose of prolonging the anesthesia.

A fresh preparation should be used. Exposure to light or air decomposes ethyl bromide and results in the formation of compounds having a more toxic effect than ethyl bromide.

A NEW METHOD OF ANESTHESIA.

J. Geppert, of Bonn (Deut. Med. Woch., 1899, Nos. 27, 28, and 29), describes, with illustrations, an apparatus already successfully used in some 400 cases (in 230 by himself), which automatically delivers air containing a large and known percentage of chloroform into a mask or the open mouth of the patient, a scale in degrees of 0.25 cubic centimeters attached to a tap indicating the exact amount of chloroform delivered per minute. The mixture is concentrated; a small quantity is required, and free respiration is a condition for its use. A gasometer is filled with air; a weighted glass rod suspended from the top of the upper cylinder of the gasometer descends pari passu with it, and plunges into a glass tube containing chloroform, the overflow of which passes into a receiver in a bath at 90° to 100° C., and is immediately vaporized. The chloroform vapor is led into the discharge pipe of the gasometer, and the mixture of air and chloroform is led to a convenient spot by fixed gas piping, and thence by a
rubber connection to the operating table. The proportion of chloroform vapor to air (0.4–0.5:1 liter) depends on the relative diameters of the cylinder and glass rod, and also upon the chloroform in the tube ‘being pure, or as Geppert employs it (mixed with ether, 2 to 1 by volume, by weight 300 grammes chloroform to 70 grammes ether). Condensation does not then occur above 10°C.

The installation of the surgical clinic at Bonn is large enough for at least six administrations of from one to two hours; the service to the operating-room is fifteen meters, where it ends in three supply taps. It is kept always ready for use. Smaller apparatus have been made, including a portable one for use in the wards. A dose less than 1.2 cubic centimeters per minute causes no unpleasant sensations, but given without preparation that amount is distressing, and 2.2 cubic centimeters is unbearable; with preparation the dose may be gradually increased.

Geppert recommends that for quiet anesthesia, free from danger, the supply of chloroform should be continuous, but only just sufficient for the case; and that it should not be interrupted unless the pulse falls below 60, or is poor in character, or the respiration becomes slow or superficial. The mask employed may be covered with fine wire gauze instead of flannel. Before it is applied the regulating tap is opened to allow the air in the conducting pipes to escape; the tap is then closed, and the mask applied in the usual way, taking care that the stream of chloroform vapor will fall below the nose, so as to mix with the air entering the lungs. Regulation is entirely by the tap, not by withdrawing the mask. A beginning is made by gradually opening the valve, till at the end of about one minute the indicator reaches 1.2 cubic centimeters per minute, when a pause is made for a couple of minutes; the indicator is then turned to 1.45 cubic centimeters, and a pause again made; and so on, the increase being made more gradually as 2.2 cubic centimeters is approached. Women are narcotized generally at 1.70 or 1.95 cubic centimeters, men somewhat later. If narcosis seems at any point nearly established, the supply of chloroform is not increased. It is particularly desirable to use as little as possible, and as much as 2.2 cubic centimeters per minute has seldom been required for women. Men require more; alcoholics have taken as much as 3.70; 4.2 has never been reached, but the longer Geppert has practiced this method the more rarely has he had to use large doses.

When narcosis has been established, the dosage that has been reached must be continued for one or more minutes, particularly if the chloroform is not administered in the operating-room. In any case one commences in the operating-room with the same dose (after flushing the conducting tube). In the first part of the operation the same dose is required, or if there be reaction to the knife, a little more; but after a few minutes it may be gradually reduced to about 1.2 cubic centimeters or somewhat higher in men, somewhat lower in women. With this stage smooth water is reached. The pulse rises above 72, respiration is frequent, the corneal reflex generally present; pupils not dilated and sensible to light. Should the latter dilate or the pulse slow, the tap may be cautiously closed. Should reaction set in it may be opened one or two degrees (0.25 or 0.50 cubic centimeters); in the later stages short intermissions of from fifteen to thirty seconds may be made. It is often necessary, especially in operations on the face and neck, during the narcosis to replace the mask by a knee-tube, the end of which can be passed into the mouth, and such a tube may be used for anesthesia through a tracheal cannula, or in the case of very nervous women who fear the mask. The average amount of chloroform vapor required in the first hour was 30 to 40 cubic centimeters, and for a two-hour operation 40 to 60 cubic centimeters, with half as much ether in each case.—British Medical Journal, Aug. 12, 1899.

REPORT OF ONE HUNDRED AND TWELVE CASES OF APPENDICITIS.

Means (Journal of the American Medical Association, Aug. 5, 1899) reports 112 cases of appendicitis, eighty-two of which were treated by operation and thirty by medicinal measures. Of the eighty-two operated cases, two died—one of acute suppulsive peritonitis, which had existed before operation, the other a case of chronic trouble from unknown causes.

Of the operative cases, thirty were acute and fifty-two were chronic or recurrent.

In nine cases the operation was performed within twenty-four hours of the attack; in five of these the appendix was ruptured.

In seventeen cases the operation was performed within forty-eight hours of the
attack; in ten of these the appendix was gangrenous.

Twenty-three cases were operated on within seventy-two hours. In twenty of these cases the appendix was gangrenous in some portion; three cases were instances of catarrhal abscesses, with more or less inflammation of the surrounding tissues.

In twenty-five cases the operation was performed after the third day, and as late as three weeks. There were abscesses in twenty of these; five cases were catarrhal; in nine cases the appendix was not removed, since it was found embedded in granulation tissue, forming the walls of the abscesses. Fecal fistulae followed in four cases. These closed spontaneously in the course of a few months.

In so far as the author has been able to ascertain, hernia followed in six cases. A mistaken diagnosis was made twice. One of these cases was a cholelithiasis, the other a pyosalpinx.

Of the thirty patients treated medicinally, eight died from septic peritonitis; twelve of the twenty-two who recovered had recurrent attacks. In five of the cases treated medicinally, operation was refused because of the hopeless condition of the patient.

It may be accepted as an established fact, according to Means, that in males peritonitis has its origin almost exclusively in the appendix. Evidence of the existence of the disease may be determined by skilful palpation. This is best made by Edebohl’s method.

The patient lies on his back with limbs flexed at the hips. Placing three or four fingers of the right hand flat on the abdomen, we feel for the margin of the right rectus muscle, in the line between the navel and the anterior superior spine of the ilium. The fingers are introduced with a light, steady pressure under the margin of the rectus until we feel distinctly the pulsation of the common iliac artery. The appendix is felt, as a rule, just outside the artery, its insertion about an inch distant, while its tip often crosses the artery. We move the fingers slowly outward as soon as we feel the pulsation of the artery, and note with care the condition of the posterior abdominal wall—that is, the iliopectineus muscle covered with the iliac fascia. This is the point of resistance against which we compress the appendix and which makes it possible to palpate it. When there is much tenderness and rigidity of the muscles, it will be almost impossible to feel the appendix; and again, if the appendix extends upward behind the colon, it cannot be discovered. However, with experience a skilful manipulator will be able to determine the outlines of the appendix in a large percentage of cases.

There are other points in the differential diagnosis that might be mentioned. Renal colic is perhaps one of the most difficult conditions from which to differentiate. We should bear in mind, however, that in appendicitis, while the pain is constant it is progressive in its intensity; and in renal colic the pain is constant the intensity is not increased. In renal colic, when the pain ceases it ceases instantly; in appendicitis it ceases gradually.

Then, again, in a limited number of cases where the appendix is behind the colon, the pain may extend to the testicle, as in renal colic. If other characteristic symptoms of appendicitis are present and the peculiar progressive character of the pain is recognized, it is possible to differentiate from renal colic.

In gall-stone colic there is nausea and vomiting, usually continuing for several days; in fact, the gastric disturbance is characteristic of disease of the gall-bladder. The location of pain in gall-stone colic is in the epigastrium, and it radiates toward the shoulder and scapula. The seat of tenderness is also usually over the gall-bladder, while in appendicitis it is over McBurney’s point.

In the female there may be some difficulty in differentiating between appendicitis and salpingitis. In the early stage the differentiation can be made much more readily than later when pus has formed. The main points of difference are the acuteness of the attack in appendicitis and its tendency to recurrence. The pain in appendicitis is more acute and the location of the tenderness is different. A vaginal examination will reveal the seat of tenderness to be in the right pelvis; while in appendicitis the pelvic organs will not be tender. Chloroform narcosis may be necessary to complete a satisfactory examination.

Means appends to his paper the following conclusions:

An early diagnosis of appendicitis is desirable and possible if the few cardinal symptoms are understood, such as pain near the umbilicus, tenderness in the ileocecal region, tympanites, and rigidity of the muscles in the lower right quadrant of the abdomen.

Too much significance should not be placed upon the presence or absence of pain, and high temperature. Both may be absent, while grave pathologic conditions are going
LAMINECTOMY FOR DISLOCATION OF THE SPINE.

Johnson (Annals of Surgery, August, 1899) reports the case of a man, thirty-two years of age, who had enjoyed good health up to the 16th of last July, when he fell from a tree, striking upon his buttocks. The injury received produced almost complete loss of motion in both lower extremities, anesthesis of the genitals and the inner surfaces of the thighs, partial anesthesis of the outer surfaces of the thighs and of the legs, with complete paralysis of the bladder and loss of control of the rectum. When the reporter first saw this patient, three months later, he had regained some muscular power in the lower extremities, so that he was able with assistance to walk a few steps. He thought that the anesthesis was slightly improved; it was, however, well marked, and no urine had been passed since the accident, except by means of a catheter. He had no control over his rectum. In the region of the lower dorsal spine there was a marked kyphosis, corresponding to the spine of the first lumbar vertebra. The distance between the last dorsal spine and the first lumbar spine was greater than normal. Palpation on either side of the spine showed the presence of two sharp, bony prominences, corresponding to the articular processes of the first lumbar vertebra, which appeared to be dislocated backward. The patient was somewhat emaciated and in poor condition generally, and it was decided that an operation might give him some relief.

A vertical straight incision, six inches in length, was made over the spines of the vertebrae, with its center over the space between the last dorsal and the first lumbar spine. The muscles were stripped away upon either side from the spines and laminae, and the bleeding checked by means of gauze packing; few ligatures were applied. After the separation of the muscles the spines and arches of the last dorsal and of the first and second lumbar vertebrae were removed with rongeur forceps. It became evident that the arch of the last dorsal vertebra was pressing forward upon the dura. Underneath the arches of the first and second lumbar vertebrae, also compressing the dura in a forward direction, was a dense mass of new connective tissue. No evidences of fracture were found. By raising the dura and exploring the anterior wall of the spinal canal with the finger and with blunt instruments a bony ridge could be felt, which appeared to be the upper border of the body of the first lumbar vertebra. The dura appeared to be markedly distended; it was punctured, and a stream of clear cerebrospinal fluid escaped under some tension. Inspection of the cord showed nothing beyond an apparent flattening. The wound in the dura was closed, as well as the wound in the remaining soft parts, by means of sutures. Primary union occurred throughout.

After the operation the patient complained of a good deal of pain in his legs. Within a week he began to urinate voluntarily, and has now regained complete control over his bladder and rectum. He walks so well that he has been enabled to resume his ordinary occupation. The anesthesis has almost entirely disappeared, and his general health is excellent.

OBSIDINATE HICCough FOLLOWING NEPHRECTOMY OF CALCULUS PYONEPHROSIS.

Despagne (Annales des Maladies des Organes Génito Urinaires, No. 7, 1899) reports the case of a man forty-three years old upon whom he operated for the relief of a pyonephrosis, the nature of which was determined only by an exploratory incision. Cystotomy was performed, the opening being along the outer border of the rectus muscle. This showed the tumor to be retroperitoneal and involving the kidney. The peritoneal opening was then closed and the
kidney was excised, access to this organ being afforded by an incision carried at right angles to the first cut in the direction of the lumbar region. The decortication of this tumor was extremely difficult, especially in the direction of the diaphragm; moreover, the pus sac was torn during these manipulations, and the whole wound was inundated with pus. The cavity left after this operation was drained. Because of the free bleeding there was much shock. This was followed by a temporary anuria. Under the influence of subcutaneous injections of about fourteen pints of serum the functional activity of the remaining kidney was reestablished. The patient began to vomit the day following the operation, and on the second day was tortured by hiccough, which was persistent and harassing for nine days. The anuria after the operation lasted sixteen hours. For twelve days the urine held albumin and granular casts. The patient recovered.

**PAINLESS LITHOTRTY UNDER THE INFLUENCE OF RECTAL INJECTIONS OF ANTIPYRIN.**

Du Chastellet (Annales des Maladies des Organs Génito-Urinaire, No. 7, 1899) calls attention to the fact that rectal and vesical irrigations or injections of antipyrin have long been recognized as potent means of lessening vesical sensibility. In the subject of his present report the following solution was injected into the rectum three-quarters of an hour before beginning the operation of lithotritry, which was performed by Guyon:

Antipyrin, 24 grains;
Laudanum, 10 drops;
Water, 3 ounces.

The crushing and evacuation of the stone was absolutely painless. The bladder seemed non-sensitive to touch and tension. The operation lasted more than half an hour, and the only inconvenience experienced was that incident to the repeated passage of instruments along the urethra.

**ULTIMATE EFFECTS OF NEPHRECTOMY.**

Verhoogen (Annales des Maladies des Organs Génito-Urinaire, No. 7, 1899) presented before the Belgian Society of Surgery a patient on whom he had performed nephrectomy for the relief of a cancer of the left kidney five years before. A tumor developed following a slight trauma, and was removed, together with the entire kidney, which was infiltrated. This growth was found to be a glandular carcinoma of the kidney with cystic degeneration. According to Verhoogen, medical literature contains only five similar cases in which survival was longer than four years. The fortunate result is attributed to the early surgical intervention, this having been practiced within two months of the injury.

The second patient presented by Verhoogen had been subjected to nephrectomy because of tuberculous pyonephrosis. The cachexia rapidly disappeared, and the patient regained all appearances of robust health. What is of far more importance, the tuberculous lesions which were manifest in other parts of the body either retrograded or disappeared completely; thus a cystitis which had been present cleared up, and the sounds of infiltration which were noted in the lungs disappeared. The hectic from which the patient suffered was cured immediately. Two other such cases have been operated on, one more than six years ago, and all have been practically well ever since.

**PROSTATIC CALCULI.**

Rousseau (Annales des Maladies des Organs Génito-Urinaire, No. 7, 1899) reports the case of a man forty-five years old who had suffered from gravel since his seventeenth year. In March, 1895, he suffered from frequent and painful micturition and vesical tenesmus; moreover, there was a free purulent discharge upon the passage of the sound in the prostatic region. A perineal cut enabled the calculus to be withdrawn; it weighed an ounce. Subsequently the calculus reformed in the prostatic pouch, and the patient died of repeated operations.

The second case had suffered for two years with hypogastric pains, increased by efforts of micturition, frequently recurring. The sound showed roughness in the prostatic region. The extraction was accomplished by the combined perineal and hypogastric routes, since the prostatic portion of the stone was united by a narrow neck to the intravesical portion.

**VESICAL CALCULUS IN AN INFANT.**

Delagrange (Annales des Maladies des Organs Génito-Urinaire, No. 7, 1899) observed a child five years old who for two years had difficulty in micturition. This difficulty became progressively worse and was associated with great pain, located especially in the perineum. The urine was passed only
after long-continued efforts, and would then come a few drops at a time; it contained no blood, and the moment the straining efforts were over the pain ceased. It was not aggravated by jolting. Exploration with bougie showed nothing but spasm of the compressor urethre muscle. Rectal examination was also negative. After repeated passages of the sound the click and rough grating of a calculus was detected. This seemed to be placed in the urethra, and for its removal external urethrotomy was performed, but the calculus could not be found. The wound suppurated, but closed in a month. Intermittent sounding was practiced, but no further sign of the calculus could be detected. Somewhat later the intravesical calculus was felt, but its presence could not immediately be confirmed by subsequent examination. Some two weeks later, however, it was felt anew, and was extracted by means of suprapubic cystotomy. It was ovoid in shape, about three-fifths of an inch long and two-fifths in diameter. Healing was by first intention, and with the exception of a bronchopneumonia convalescence was uninterrupted.

A CASE OF VESICAL TUBERCULOSIS CURED FOR FIVE YEARS BY INJECTIONS OF IODOFORM OIL.

Jamin (Annales des Maladies des Organes Genito-Urinaires, No. 7, 1899) states that injections of iodoform oil in the treatment of tuberculous cystitis have in several instances enabled him to obtain in a few months a cessation of all symptoms of cystitis and the total disappearance of the Koch bacilli. The subject of his present report has been well for more than five years, although at the time she came under treatment she exhibited the symptoms, signs, and bacteriological evidence of tuberculous cystitis. At first instillations with weak bichloride were tried, but this drug was not well tolerated. Iodoform suspended in liquid vaselin, five parts to a hundred, was then employed. No inconvenience of any kind was experienced, although from one to two teaspoonfuls was employed at a time. The injections were given at first daily, then every second day. The quantity of bacilli steadily diminished, and finally these germs disappeared completely. At the same time the symptoms of cystitis had become insignificant and micturition had become normal and painless.

In the course of four and a half months sixty-two iodoform injections had been administered. In the next year these injections were given about once a week. The following year the patient was seen about twenty times and was given an injection each time. The urine by this time had become perfectly limpid, and the general health had enormously improved.

This case seems to prove conclusively the admirable results which may follow such a course of treatment. Although Jamin has injected many other bladders in the last six years with this same preparation, he has no other equally successful case to present. Often the amelioration is most striking.

Guald, in commenting upon this communication, adds his testimony in favor of the iodoform oil injections. He especially calls attention to the innocuousness of this means of treatment. It causes no inflammatory reaction and usually produces an immediate lessening of painful sensations and reflexes. This forms a marked contrast to the use of the sublimate solution, which, though often efficacious, will produce on occasion pronounced reaction and distinct augmentation of kidney symptoms.

INFLAMMATION OF THE BURSA GASTROCNEIMO-SEMIMEMBRANOSA.

Hawkes (Annals of Surgery, July, 1899) reports four cases of this affection cured by excision. It is an affection which rarely occurs in literature.

The gastrocnemio-semimembranosa bursa is situated between the inner head of the gastrocnemius and the tendon of the semimembranosus muscle, and when distended furnishes a very large percentage of all bursal swellings situated in the popliteal region. It lies at the bottom of the so-called popliteal internal sulcus. This sulcus or depression has for its inner wall the shelving inner head of the gastrocnemius, and for its outer the cord-like mass of the inner hamstring tendons as they cross the back part of the knee-joint. It is best seen and felt when the patient is in the standing posture, with the full body weight borne on the lower extremities; the limiting muscles are thus made prominent and so deepen this internal popliteal sulcus, at the bottom of which lies the bursa, its center being about on a level with the upper articular surface of the tibia. It is shaped somewhat like the letter U, and rests astride the outer and tendinous border of the inner
head of the gastrocnemius, at the point where the tendon of the semimembranosus muscle overrides this border on its way to its tibial attachment below, one of the limbs of the U resting on the anterior surface, the other on the posterior surface of the gastrocnemius in this position. Its inner surfaces are normally everywhere in perfect contact, and are sufficiently lubricated by the so-called "synovial secretion" to permit the necessary gliding motions between adjacent structures without undue friction.

In size this bursa averages one to one and one-half inches in the long axis of the limb, and about three-quarters of an inch in the transverse. It is sometimes much larger, and this is particularly noticed in muscular subjects. It is sometimes multilocular, with the various cavities communicating or occasionally separate from one another. The two limbs of the U may be separated by a so-called "diaphragm" of varying thickness, often perforated at or near its middle. Bands are also seen occasionally in the sac crossing from one side to the other.

While consisting often of a closed sac, it occasionally communicates with the knee-joint; this communication, according to Gruber, being found in about one-third of these bursae, and being most frequently encountered in well developed male adults.

While not communicating directly with the knee-joint capsule, this bursa may communicate with the bursa directly above it; which almost invariably either leads directly into the knee-joint, or is separated therefrom by a membrane so thin as to offer feeble resistance to the spread of infection.

Overaction is usually the starting-point of bursitis. This overaction may be in the form of prolonged and unusual use of the joint, or of some sudden extreme effort. In other cases there is no apparent cause, and this should suggest the possibility of tubercular, rheumatic, or luetic infection.

When this bursa becomes distended it appears first at the bottom of the internal popliteal sulcus as an oblong cystic swelling, which projects more and more into the popliteal space, until it occupies a large portion of it, the bulk of the swelling being, however, to the inner side.

A position of hyperextension of the knee causes the swelling to project to its utmost. Over it the skin and fatty layers are freely movable. A characteristic sign of this tumor is the firm attachment of its base to the inner hamstring tendons.

The contents of the bursa can sometimes be reduced into the knee-joint, when there is a free communication with this cavity; the position most favorable for this is one of semiflexion of the knee. This sign of reduction is not to be relied upon unless it is most marked, nor should absence of this sign be construed as proving that there is no communication between the bursa and the joint.

Fluctuation can usually be detected, and sometimes the movable bodies so common in these bursae can be felt. There is rarely much pain. The patients complain rather of a sense of discomfort, of pressure, and of limited motion; moreover, the knee feels weak. As the tumor increases in size, swelling of the leg and foot may develop as a result of pressure.

A popliteal bursa usually shows itself, when distended, as a deep elastic tumor, situated farther down in the calf of the leg.

Distention of the gastrocnemio-condylar bursa alone can scarcely be diagnosed apart from the accompanying knee joint distention, on account of its deep situation under the gastrocnemial head, and from the fact that, as a rule, it either communicates with the knee-joint by a free opening, or is separated from it by such a delicate membrane that any increase of tension within the bursa would in all probability cause the bursal contents to gain access to the knee-joint.

Distention of the bursa between the semimembranosus tendon and the head of the tibia might present signs very similar to those under consideration. Hawkes has not been able to find a recorded case.

As to the treatment of this affection, which is sometimes bilateral, Hawkes rejects all methods excepting excision of the sac after compression and counter-irritation have failed. The limb is emptied of its blood by an Esmarch bandage and kept in this condition by the rubber tourniquet. The patient is then turned on the sound side and the knee is held in a position of forced extension by an assistant. The skin incision is made in the long axis of the limb over the most prominent part of the tumor, curving a little more to the inner side of the knee below so as to be over the origin of the bursa at this point. The tissues are divided down to the popliteal fascia and the upper portion of the cyst is exposed. The cyst is then freed of its adhesions without opening into the bursal sac until it has been freed from the semiaponeurotic surface of the gastrocnemius,
on which it lies in part, and from the upper three-fourths of its attachment to the semimembranosus tendon. This brings the cyst down to a pedicle of moderate size, and dissection is much facilitated if the contents of the sac are evacuated and its inner walls explored for openings communicating either with the knee-joint or with the bursa directly above. Where no such openings are found, the further dissection of the cyst wall is best carried out by introducing a finger of the left hand into the cavity of the bursa and pulling the remaining pouch over it like a glove finger. In this way the whole bursal wall may be removed with the least damage to the tendinous structures at its origin, and with a minimum risk of opening into the synovia of the knee-joint. Where a joint communication is clearly detected or seems probable from previous signs, a catgut ligature should be thrown around the pedicle at this point and the sac cut away. If there be found an opening into the bursa above, it is to be similarly treated, because of the usual communication of this latter bursa with the knee-joint; or such bursa may in turn be dissected out and its opening into the knee-joint closed. Slight flexion at the knee-joint should facilitate this part of the work, relaxing the gastrocnemial fibers under which this second bursa lies.

MODIFICATION OF PLASTIC OPERATIONS ON THE LIPS.

Silberberg (quoted in the Medical News, Aug. 5, 1899) suggests a modification in the technique of operating for cancer of the lips, which shall give a complete red edge to both lips. It is only possible when the angle of the mouth is not excised. For instance, after the usual V-shaped incision of a growth in the lower lip, a double-edged knife is passed through the upper lip, at a little less than an inch from the angle of the mouth. The blade is passed obliquely so that the mucous surface shall be wide. The incision is made along the red border to the angle of the mouth, and then on out into the cheek for an inch or more, and thence downward toward the point of the chin in a line parallel to the edge of the V-shaped wound made by the removal of the growth. Such a cut is made in both cheeks, and when the gap in the lower lip is closed by bringing together these flaps from both cheeks the angles of the mouth will be shifted from their usual positions to the points in the upper lips where the incisions began. The two lips thus being made of equal length, deformity of the mouth is avoided. This principle of operation can be adapted to any of the incisions about the mouth, which leave its angles intact.

HERNIA FOLLOWING OPERATIONS FOR APPENDICITIS.

Harrington (Boston Medical and Surgical Journal, August, 1899) states that at the Massachusetts General Hospital from January, 1888, to August, 1897, 503 cases of appendicitis of all varieties recovered after operation by the various surgeons. He personally examined 236 of these cases, and received letters from 139 others. He found that many who had reported themselves as perfectly well had marked general bulging of the abdominal wall on the side operated upon. Some had protrusions of the wound, and some had hernias of which they were not aware, as they caused no trouble.

Of the 236 cases examined, eighty-five were tightly closed at the time of operation; eighty-eight were partly closed at the time of operation; and sixty-three were open wounds. There were fifty-two cases of bulging in the wound—twenty-seven to a slight extent, and twenty-five to a marked extent. There were twenty-seven cases of true hernia. Most of these, as was the case with the bulging, developed in the wounds which had not been closed at the time of operation. The wounds partly closed were followed by fewer hernias than open wounds. Weakening of the abdominal wall existed in a large percentage of the cases which were drained. The muscular and tendinous fibers should not be transversely cut in any appendix operation unless it is unavoidable.

As little drainage material as safety will permit should be used. When drainage is necessary the wound should be closed as far as possible with sutures and the drainage removed as early as safety will permit. If the wound can be closed immediately the tissues should be restored to their normal position by suturing each layer.

Stout belts and trusses are of little value and may even do harm.

The abdominal muscles from the earliest period possible after operation should be developed by appropriate exercises.

If hernia or marked bulging appears, operation for cure is safe and satisfactory.
GAstrIC UlCer AT THE MASSACHUSETTS GENERAL HOSPITAL.

Greenough and Joslin (American Journal of the Medical Sciences, August, 1899) append to an interesting study of the records of the Massachusetts General Hospital a comparison of these records with those of other institutions. They have published the following conclusions:

Gastric ulcer is more frequent in Boston than in Chicago, Baltimore, Denver, or San Francisco.

It is five times as common in women as in men.

The average age in men is thirty-seven years; in women twenty-seven.

Hemorrhage was present in eighty-one per cent of the cases. It caused the death of seventeen per cent of the male patients, but only 1.27 per cent of the females. No woman under thirty died of hemorrhage from gastric ulcer during this period.

The blood was that of a chlorotic type of anemia.

Perforation occurred in 3.2 per cent of the cases, and none of these patients left the hospital alive.

Of 114 patients eighty per cent were discharged cured or relieved, but at the end of an average period of five years only forty per cent remained well. The mortality at the same time (due to gastric disease) was twenty per cent; among the males it was thirty per cent, with the females nine per cent.

The excessive mortality of ulcer among men, its occurrence in life a decade later than in women, and the absence of fatal cases of hemorrhage in females, point to a difference of the ulcer in the two sexes.

The mortality of eight per cent, and the failure of medical treatment to effect a lasting cure in sixty per cent, of the patients indicate the need of surgical intervention in other than emergency cases of this disease.

THE PRINCIPLES OF THE TREATMENT OF INJURIES OF THE SPINAL CORD.

Bolton (Annals of Surgery, August, 1899) states that so far as a spinal injury itself is concerned, the rules governing the treatment of fractures, dislocations, and distortions hold perfectly good within the limitations imposed by the anatomy of the spine, and that from this point of view there can be no reasonable objection to reduction by operative measures, if need be. So that this part of the problem may be dismissed without further discussion.

The cord injuries, however, occur in such variety, and their symptomatology is often times so puzzling, that confusion in the identification of the lesion present has sometimes led to the adoption of methods of treatment whose results have been most misleading.

The repair of injuries of the cord after division is by the growth of ordinary cicatrical tissue.

Extra-medullary hemorrhage occurs oftenest between the dura and the wall of the spinal canal, far less often within the dura. It is yet to be proven that hemorrhage between the dura and the bone ever occurs in sufficient volume to give rise to symptoms referable to the cord by causing compression. The bleeding occurs chiefly from veins of small size, and is capable of wide distribution before it can exert pressure upon the cord.

Complete lesions of the cord occur most commonly in fractures and dislocations of the vertebrae, the result of forced flexion of the spine, in which the affected portion of the cord is crushed against the body of the lower vertebra by the arch of that above or by fragments of vertebra or intervertebral disks displaced into the canal.

A similar result may be produced by a direct or indirect fracture of the lamina of a single vertebra with depression of the fragment into the spinal canal upon the cord.

The cord is pulpiified within the pia, and disintegration of the cells and fibers in the affected area immediately follows. There is no regeneration of nerve elements, repair taking place by the growth of ordinary connecting tissues.

Incomplete lesions of the cord occur at times under the conditions named above, but are more incident to stab or bullet wounds or distortions of the spine. Degeneration occurs above, below, and beyond the lesion, and repair takes place by the growth of scar tissue. The directly injured cells and fibers are lost.

Hemorrhages in the cord as a rule occur in the gray matter. Their site is at the cervicodorsal or dorsolumbar junction, in those portions of the cord corresponding to the most freely movable parts of the spine; and this fact points to their probable etiology by overtension in the axis of the cord.

Along with hematomyelia there may be, and not infrequently is, more or less confusion of the cord.
Considering these lesions from the viewpoint of their amenability to treatment, it appears that extradural hemorrhage does not give rise to cord lesions or symptoms, and requires no treatment.

Total lesions of the cord are irremediable, because the cells and fibers of the entire thickness of the cord are destroyed, are never regenerated, and are replaced by cicatricial tissue. The lesion thus is permanent and requires no treatment.

In hematomyelia the clot is absorbed; its site persists as a cavity or is filled by newly formed tissue; irregularities of circulation in the surrounding portions of the cord adjust themselves. There may be great amelioration of the symptoms.

There is therefore no therapeutic indication, and no remedial treatment is possible.

In partial contusion of the cord the lesion results in permanent destruction of cells and fibers; disturbances of circulation adjust themselves. Repair is accomplished by cicatricial tissue. No treatment is available.

In open injuries of the cord there are destructions of cells and fibers and disturbances of circulation. In addition, infection may occur or a foreign body be introduced and left in or lodged against the cord, and by its continued presence produce great disturbance of circulation and consequent extensive degeneration and necrosis of cells and fibers. Repair occurs by cicatricial tissue as before.

But here active operative interference is indicated to remove foreign bodies, to facilitate disinfection, to prevent more extensive necrosis, and to facilitate drainage.

TRAUMATIC RUPTURE OF THE COLON.

Makins (Annals of Surgery, August, 1899) has successfully treated in the last three years two cases of rupture of the ascending colon. In his second case, not previously reported, the indications for exploration were the nature and history of the injury (the force had been severe and applied to a strictly local area which was marked by a distinct abrasion), frequent and early vomiting, early development of the rigidity of the abdominal wall, local tenderness, impairment of resonance in the right iliac region, the absence of definite signs of injury to the urinary bladder or solid viscera, combined with the evidence of serious injury as indicated by the degree of shock. Abdominal pain, rise in pulse, general pallor, and perspiration. On opening the abdomen there was a well marked fecal odor, and a large amount of plastic lymph had developed on the surface of the coils of the small intestine lying in the right iliac region, and the pelvis on the right side. The operation was undertaken seven hours after the injury. Makins, as a result of study of the records of the St. Thomas Hospital between the years 1889 and 1898 inclusive, finds that of the 8153 cases of injury to various parts of the body treated in the hospital, 292 (3.9 per cent) were injuries of the abdomen. Of these 292 cases, eighty-nine were ruptures either of the abdominal viscera or urinary bladder. Of the eighty-nine cases, twenty-one were ruptures of the intestine, of which six were the result of kicks by horses, five were run over, four fell, two were caught between buffers, one was struck by the end of a plank on a sawing machine, one was pinned by the pole of a van against a wall, one was struck by a falling box, and one was caught and rolled between two passing railway trucks.

Of the twenty-one cases, the small intestine was ruptured in sixteen, the large in five. A consideration of the points elucidated by a study of these cases shows that the actual determining elements as to the part of the intestinal tube likely to be injured are that the violence be exerted on that part of the belly cavity supported by a bony wall posteriorly, and hence, that the bowel to be injured should either be fixed in the lower half of the abdomen or possess a sufficiently long mesentery to lie in that region.

Blows over the abdomen above the level of the umbilicus are very unlikely to cause a rupture of the intestine, unless the violence be so directed as to allow the gut to be directly compressed against the spinal column, a matter of some rarity. If blows so directed are received, injury to the mesentery or omentum is at least equally as probable as one to the bowel itself.

In none of the cases was there a large extravasation of fecal contents. In six cases shock was severe, in eight cases it was slight, and in three it is definitely stated that there was no shock. Abdominal pain is a constant sign, but not necessarily either severe or continuous. Rigidity and immobility of the abdominal wall are almost constant, but are not pathognomonic of the injury. Abdominal tenderness is to be regarded as a constant sign, but is often obscured by injury which is present in the abdominal wall.
In all cases the pulse shows a steady tendency to rise in frequency and lose in strength, practically in an identical manner to that in which it acts in other cases of peritoneal sepsis. This is regarded by Makins as the most important single sign in the question of deciding on abdominal exploration.

A definite diagnosis between simple rupture of the intestine and rupture of the mesentery is often impossible. The latter condition, however, is suggested by the presence of a large quantity of free blood in the peritoneal cavity, since uncomplicated ruptures of the intestine are rarely accompanied by free hemorrhage. The violence is usually a crush or gliding force, such as a wheel passing over the abdomen.

Of the fifteen cases operated upon, there were three recoveries, or twenty per cent.

The operation should be performed if rupture is either diagnosed or suspected. A median incision between the umbilicus and the pubes, in or slightly to one side of the linea alba, is generally to be preferred. After opening, the site of the rupture is suggested by the presence of the plastic lymph, which is developed early, and especially in the neighborhood of the rent, and often by local peritoneal effusion, which may be foul-smelling. Moreover, blood is usually present in small quantity near the seat of rupture, and from the opening gases may escape.

In the presence of retroperitoneal emphysema, pointing to injury to the colon or duodenum outside the limits of their peritoneal covering, Lemert's suture is to be preferred in closing the wound.

When surrounding contusion is severe, or complete transverse solution has occurred, resection of a suitable portion of the gut should be followed by closure of the ends of the cut bowel, and the establishment of a lateral union or anastomosis, either with Halsted's suture or a Murphy button.

The abdominal cavity is best cleansed by a preliminary dry sponging of the obviously infected area, followed by irrigation, and, if necessary, the protrusion and washing of the small intestine and thorough flushing of the pelvis and various peritoneal fossae. Irrigation prior to the dry cleansing of the most severely affected area is to be avoided.

Drainage is to be avoided if possible, but if, from the extent of the infection or the special distribution of it, it is deemed necessary, it should be abundantly provided for by means of a gauze plug.

In the after-treatment shock is best com-

bated by saline infusions. Rectal feeding should be relied upon for the first twenty-four hours; after this period fluid nourishment may be administered by the mouth.

Morphine should be avoided if possible, and should distention and sickness herald the advent of septic infection, saline purgation should at once be resorted to as in other cases of peritoneal sepsis. Sulphate of magnesia may sometimes be retained, even when vomiting is troublesome, by washing out the stomach preliminary to administering each dose.

NEPHRALGIA.

Hubbard (Annals of Surgery, August, 1899) publishes a history of five cases of nephralgia occurring in the Massachusetts General Hospital.

In the first case there was a history of renal pain and the passage of gravel and small stones, aggravation of the pain on motion and jarring, and pus and blood in the urine, the latter at times in large quantities. This patient was operated upon in 1891 for stone, but none was found. He remained well for seven years, when he had a relapse, passed blood and pus, and lost thirty pounds in weight. He then passed some gravel, and since that time has been free from pain, passes clear urine, and has gained in weight.

The second case had a sudden pain in the right loin running down to groin and testis five years ago, which pain was accompanied by vomiting. The second attack followed in a year, and since then these attacks have been monthly. He never passed gravel nor had any trouble with micturition. The urine was normal and there was no kidney tenderness. He was operated upon in 1894, but the kidney was not opened. Three months after leaving the hospital there was a reminder of the attacks, another three months later, and since then this patient has remained well.

The third case gave a history of passing bloody urine, and every three weeks or so had severe pain in left side. There were recurrences of the pain in the left side, and coincident with these attacks of pain the urine became bloody, and large clots were passed. He was operated upon in 1895. The needle grated on something as it explored the kidney, but an incision one and one-half inches long, through the posterior edge and pelvis of the kidney, failed to find the stone. The patient reported that he had had a few attacks of bleeding.
The fourth case suffered from pains across the back and passage of gravel, the largest piece the size of a pea. His pain was greatly aggravated by jolting. The urine contained pus. He was operated upon in 1897. The kidney was needled, but no stone was felt. The kidney was then incised and explored by the finger, with negative result. A year and a half later he reported that he was entirely free from pain and troubled less from frequency of micturition.

The fifth case gave a history of renal colic so severe as to require hypodermic injections of morphine. No blood, stones, or gravel had been noticed in the urine. He was slightly tender over the region of the kidney behind. At one time a few red corpuscles were found in the urinary sediment. He was operated upon in 1897. The kidney was incised along the convex border from the middle to its lower edge, and explored by the finger, but no stone was felt. A year and three-quarters later the patient wrote that he had gradually improved and had no pain in that side. He had suffered from a severe attack of pain in the other side and passed some blood.

Of the five cases, Hubbard considers that three have been cured and two relieved, with still some doubt as to the final outcome in both of them.

These few cases are scarcely sufficient either in number or in careful and detailed study to form the basis of a differential diagnosis and treatment.

**Pancreatic Apoplexy.**

Rasumowsky (Archiv für Klinische Chirurgie, 59 Band, 3 Heft) reports in detail a case of pancreatic apoplexy occurring in the person of a doctor. He considers this affection as distinct from the more commonly recognized but none the less rare hemorrhagic pancreatitis.

The patient had suffered since youth from acute and chronic indigestion. Following a very moderate indulgence in eating and drinking, he was seized with pain in the epigastrium, which in a few hours increased to first crippling and then agonizing intensity. There was vomiting; the bowels were freely opened by castor oil. There was dulness on percussion over the stomach, especially in the right nipple line, and this part of the abdomen was markedly distended, producing a distinct contrast with the lower part of the belly, which even seemed retracted.

The pulse mounted rapidly from 80 to 120 and 150 beats to the minute, and shock was so pronounced that the patient's life was despaired of. There was constant vomiting, suppression of urine, and dyspnea. Under active stimulation and the use of opium for the suppression of the agonizing pain, the patient rapidly recovered.

The temperature, which had fallen to 95.5°, became normal, and after nine days the patient was able to leave his bed. On the twenty-second day following his attack he took a ten-hour railway journey and consulted Rasumowsky, who with the help of two therapeutists and three surgeons noted general emaciation, pronounced anemia, and a projecting tumor in the epigastric region, most pronounced to the right of the middle line. The swelling extended to both sides, reaching to a little beyond the line of the nipple. It was most marked when the patient was in the standing posture.

Liver dulness was continuous with that of the swelling.

The relation of the stomach and tumor was not determined. An incision was made first over the most prominent part of the tumor. As this did not afford proper access, a second cut was made in the middle line. The lesser omentum was found tightly stretched over the surface of a fluctuating growth.

The diagnosis made previous to operation was of a gastric ulcer. To enable the surgeon to evacuate the pus which was suspected to exist, and at the same time to protect the general peritoneal cavity from infection, the Paquelin cautery was used in making an incision through the thin border of the left lobe of the liver. Blood and clots escaped together with necrotic portions of pancreatic tissue, as was subsequently determined by microscopic examination.

The cavity was stuffed with gauze, and the patient made a slow but uninterrupted recovery, though for three days he complained of severe pain similar to that which he had experienced during his acute attack. A small fistula due to the presence of two ligatures did not heal for five months.

An interesting discussion as to the relation of pancreatic cyst and pancreatic hemorrhage follows the report of this case. The author holds that both traumatic and idiopathic hemorrhage into the pancreas may be the starting-point for the development of cysts.

As to the diagnosis, the idiopathic hemorrhages are commonly preceded by dyspeptic symptoms for months, often for years.
Diagnosis is made or can be suggested by the seat of pain, and particularly by epigastric distention and tumor. Rasmowsky states that surgical intervention during the acute period is not advisable. The cases in which an operation was practiced, usually on the basis of a mistaken diagnosis, ended fatally. The bleeding does not take place from a single large vessel but from a number of small branches; hence if it could be reached it could not easily be checked.

During the acute period, stimulation, subcutaneous and rectal injections of normal salt solution, and, if Massé's theory as to the etiology of the hemorrhage (i.e., the action of hydrochloric acid on the tissues of the glands) be accepted, injections of soda solution into the stomach and into the veins would be indicated.

After the acute period has passed surgical intervention is absolutely necessary, since the resorption of the large exudate can scarcely be counted on, and, moreover, infection of such an exudated place near the alimentary canal is extremely likely to occur.

This large exudate not only interferes with the functions of the stomach, but gives rise to symptoms of intestinal occlusion. Moreover, by its pressure upon the thoracic duct it may interfere with absorption of the chyle from the intestine; thus would be explained the marked anemia frequently characteristic of these pancreatic cysts.

The place at which these cysts should be opened must depend upon their position. On general principles Gussenbauer's route is to be preferred—beneath the greater curvature of the stomach and between this organ and the transverse colon. Sometimes the route through the lesser omentum or even through the liver itself may be easier.

Many of these apoplectic collections of blood may be best reached from the lumbar region. Removal of clots and of fragments of pancreatic tissue should be accomplished with great gentleness. If bleeding occurs irrigation with hot water and firm packing are indicated.

THE OPERATIVE TREATMENT OF VARIOUS INTERNAL DERANGEMENTS OF THE KNEE-JOINT.

Walsham (British Medical Journal, July 29, 1899) classifies the derangements of the knee-joint which are amenable to surgical intervention as follows:

Loose bodies; detachment or displacement of the semilunar cartilages; enlargement with nipping of hypertrophied synovial fringes; and elongation of the ligamentum patellae.

All of these conditions may be attended with somewhat similar symptoms, namely, effusion into the synovial sac, a feeling of weakness or disability in the joint, some limitation in the range of flexion and extension, pain, often sudden, and even excruciating during certain movements, and at times a sensation of something slipping in or around the joint. There is, further, generally a history of some injury more or less severe, such as a fall or blow on the knee, or a sudden strain or twist of the joint.

The most obvious sign, perhaps, attending the various derangements is the synovial effusion, and the case is probably diagnosed, and correctly, as one of synovitis; but it is synovitis and something more, and unless this additional something is made out, except it consists in a mere rupture of some ligamentous fibers, the routine treatment of synovitis will not as a rule cure the patient. The progress of such cases is this: after treatment by rest, evaporating lotions, bandaging, perhaps a splint, the synovitis subsides, but recurs as soon as the patient begins to get about, recurrence being then often attributed to a fresh twist or strain. It is usually after there have been several such recurrences that these cases have come under notice.

Where a loose body is the cause of the trouble the diagnosis is usually easy. It can be felt as a rule, as we all know, to slip about in the joint, not only by the surgeon, but by the patient himself. The diagnosis is not, however, always obvious.

The diagnosis between a detached semilunar cartilage and a hypertrophied synovial fringe is sometimes far from easy. The characteristic signs of a detached semilunar cartilage as given in our text-books—namely, a sudden locking of the joint and evident projection of the displaced cartilage—is not common. More often the diagnosis has been based on a peculiar creaking or sudden click or snap over the inner portion of the joint combined with a partial locking and some limitation of movement, and perhaps slight swelling or pain on pressure over the situation of the cartilage.

The signs of hypertrophied synovial fringe are very similar, but there is not as a rule any locking of the joint, nor much, if any, limitation of movement, and the fringe may frequently be felt to roll like a soft pad under the finger when applied over the line of the articulation. The disability, however, is at
times quite equal to that produced by a displaced cartilage; but it will be found on careful questioning that the pain only occurs when the joint is semiflexed, and then not unless the semiflexion is combined with some slight lateral twisting of the tibia on the femur—that is, the semiflexion separates the articular surfaces and the twisting movement carries the hypertrophied fringe between them, where it becomes nipped when the limb is again straightened.

More than one fringe, it is well to remember, may be present; indeed, at times a series of fringes extending from the articular surface along the margin of thealar ligament may exist.

An elongation of the ligamentum patellæ is less common, but as it gives rise to symptoms similar to those of the other conditions mentioned, it may be readily confounded with them. As in the case of a loose body, a detached semilunar cartilage, or nipped synovial fringe, the patient may fall to the ground with sudden pain, the joint becoming momentarily locked. It will be found on careful inquiry that what really happened here was that the patella, consequent upon its elongated ligament, momentarily slipped over the external condyle, allowing the patient to fall. On measuring the ligament will be found half an inch to an inch longer than that of the opposite limb; and when the patient sits with the knee flexed at a right angle, the patella rests on the front surface of the condyle, so that its anterior surface, instead of being directed forward and slightly upward as in the normal knee, will be found to look directly upward.

For all these conditions, excepting the last, it may sooner or later become necessary to open the knee-joint if a radical cure is to be obtained. If a loose body is present its removal is practically the only reliable method of giving relief. When an apparatus has failed, when a patient is unwilling to give up athletic exercises, or is a candidate for the services, or is going abroad where apparatus could not be readily mended, or is engaged in such occupation as necessitates mounting scaffoldings, ladders, etc., where the breaking of his instrument might subject him to sudden locking of the joint and to a consequent serious fall, the joint should be opened without delay.

With proper precautions the knee may be freely exposed and explored with a reasonable degree of certainty that no harm will result. The precautions are the five following:

1. Preparation of the Patient.—He should be confined to his bed or couch for three or four days to a week, the secretions and diet regulated, the limb firmly secured to a Macintyre or such other back splint as it is intended he should wear after the operation, and the skin in the region of the incision rendered thoroughly aseptic. Neglect of these precautions may lead to most serious consequences. If any synovial effusion is present, this should be got rid of by appropriate treatment before the joint is opened. If this is not done there is considerable risk of septic trouble spreading to the interior of the joint should any superficial stitch suppuration accidentally occur.

The ascepticizing of the skin, it goes without saying in these days, is of the highest importance, especially in hospital patients, in whom the skin of the knee is often thickened and begrimed, and many washings and purifications are necessary to get rid of the excessive epithelium.

2. Arrest of all hemorrhage before the capsule is opened by forcipressure, torsion, or ligature, if necessary, and the thorough cleansing of the joint after the operation from all blood-clot by thoroughly flushing out the cavity with a warm mild antiseptic lotion, such as boric acid.

3. Accurate Suture of the Synovial Membrane and Capsule.—Silk may be used with safety if kangaroo tendon is not available. The serous surfaces of the synovial membrane should of course be placed in contact, and the capsule drawn together by the continuous method of suture.

4. Absolute rest on a well-fitting backsplint till the skin wound is soundly healed, firm pressure being applied by a bandage over the joint to prevent oozing.

5. Early Passive Movements and Massage.—These are usually begun on the fourteenth day, the patient being up and walking about on the twenty-first day. The early movement is most essential to success. It prevents the formation of adhesions, whilst the massage promotes absorption of any excess of inflammatory products in the healing of the wound.

OPERATIVE INTERVENTION FOR TUBERCULOSIS OF THE KIDNEY.

In an editorial in the Medical News of August 12, 1899, based upon a communication of Reynolds printed in the same journal, the writer thus comments upon the present
status of operative interference in cases of renal tuberculosis:

"We no longer believe that microorganisms can pass through a healthy kidney, and therefore when we are able to demonstrate in the urine taken directly from a ureter the presence of tubercle bacilli, it points infallibly to the existence of a tuberculous focus somewhere in the urinary tract of that side. The indication thus furnish for nephrectomy is an absolute one.

"It must be remembered, moreover, that the recent labors of Caspar and Nitze in Berlin, and of their followers all over the medical world, have made it evident that catheterization of the ureters in the male is very often, certainly in a majority of cases, not only possible but comparatively easy. The collection of the urine directly from the ureter gives much more reliable information than does even an exploratory incision, since the external surface of the kidney when exposed to inspection may be perfectly healthy, and yet a tuberculous focus exist in the interior of the organ. Communications of pathologic processes occur much more readily with the pelvis of the kidney than they do with its external surface. When the tuberculous foci are very limited in extent and therefore most hopeful for operation, they will often permit the discharge of tubercle bacilli into the urinary passages. The chances for early diagnosis and operation are with this method rendered very promising indeed.

"It would seem, then, to be only a question of a short time until the puzzling cases of progressive tuberculous renal trouble running their course without any definite pathognomonic symptoms that reveal the real cause with any assurance to ordinary diagnostic methods will cease to be the opprobrium medicine they have been up to the present time. The most striking uniform symptom in such cases is often a hopelessly aggressive emaciation, which yields to no medicinal treatment, and so makes them veritable nightmares for the medical attendant having them in charge."

PERITONEAL ADHESIONS FOLLOWING CONTUSION OF THE ABDOMEN.

NOCAK (Centralblatt f. Chirurgie, No. 37, 1899) notes that contusion of the abdomen is often followed by extensive adhesions gluing the intestines together or to other organs within the abdominal cavity, and causing persistent and exhausting colic, and obstinate constipation. He reports four cases of this nature operated on by Crédé. The adhesions were freed, and the patients were either greatly relieved or completely cured. It is noteworthy that the symptoms often developed long after the injury, and, indeed, at a time when the patient had almost forgotten it.

THE EARLY RECOGNITION AND MANAGEMENT OF MALIGNANT DISEASE OF THE DIGESTIVE SYSTEM.

EINHORN (New York Medical Journal, July 29, 1899), after calling attention to the diagnostic helps afforded by the stomach tube and the chemical analysis of the gastric contents, states that our methods are still comparatively crude, and as a rule permit us to recognize the malignant affection at a stage when it has already progressed to a considerable extent. The conditions under which the diagnosis is justifiable are summarized as follows:

Gradually developing dysphagia and the presence of a stricture in the esophagus, especially if a particle of tumor showing the characteristics of cancer has been brought up with the tube, or the above symptoms, with frequent small hemorrhages, make the diagnosis of malignant disease positive.

With reference to the stomach and pylorus, the following rules upon which to base a positive diagnosis of cancer are suggested:

1. If particles of tumor are found (in the wash water or in the tube) which under the microscope reveal the characteristic picture of a malignant growth.

2. The presence of a more or less large tumor with an uneven surface, belonging to the stomach and associated with dyspeptic symptoms.

3. The presence of a tumor associated with frequent hematemesis.

4. Constant pains, frequent vomiting, ischochymia, emaciation—all these symptoms being quite permanent and not extending over too long a period of time (six months to a year).

5. Tumor and ischochymia.

6. Emaciation, ischochymia, presence of lactic acid.

7. Constant anorexia and pains, not yielding to treatment, accompanied by frequent small hemorrhages of coffee-ground color.

For the small and large intestines the following points will prove of service in making the diagnosis of cancer:
1. If by abdominal or rectal palpation a tumor can be detected which is situated in the small or large bowel, and accompanied by symptoms of cachexia and disturbances of defecation,

2. The presence of a tumor as just described, and the discovery of small particles of the neoplasm in the evacuation giving microscopically the appearance of a cancerous growth.

3. Gradually increasing disturbances of the bowel for a few months in a heretofore healthy person, accompanied by cachexia and symptoms of a beginning or already developed stricture of the bowels, and the presence of a small particle of growth in the stools giving as above, microscopically, the picture of cancer.

After having thus summarized the conditions under which a positive diagnosis of malignant disease of the digestive system can be made, let us see how the diagnosis can be established early. There are no new points which can be suggested for this purpose. A thorough examination of the physical state of the patient—paying strict attention to all our usual methods in this direction—and a full knowledge of the history of the case, will permit us to discover malignant disease comparatively early. In quite a number of instances we shall not be able to make a positive diagnosis of cancer, but our suspicions of a malignant trouble will be aroused. Here frequent examinations and further observation of the case are of intrinsic value. Sometimes examination under narcosis may afford better results. In rare cases, in which a probable diagnosis of malignant disease can be made, an exploratory laparotomy with the view of establishing the diagnosis and performing a radical or palliative operation will be required.

Having made the diagnosis of malignant disease, the question arises, What shall be done for the patient? The following may be given in brief as an answer applicable to the digestive system in general:

1. Whenever the tumor is accessible for operation, and there is the slightest hope of curing the patient, the complete extirpation of the growth should be performed.

2. If the tumor is not accessible for operation, or the entire removal of the malignant disease is practicably impossible, palliative operations will serve to alleviate suffering and prolong life, and should be undertaken in cases requiring them.

3. Cases of malignant disease operated upon, as well as those without operation, require for their treatment and management a skilful physician, who is able to lessen suffering and nearly always also to lengthen life, even under the most trying conditions.

Cancer of the esophagus and cardia does not for the present permit of any radical operation. As soon as the diagnosis is positive and the dysphagia is such that the patient is not able to partake of sufficient liquid and semiliquid food, in order to maintain his weight, gastrostomy should be performed wherever feasible.

Cancer of the stomach and the entire intestinal tract should be operated upon, if discovered early enough. Practically the outlook for a cure after a radical operation of some portion of the intestinal canal becomes less encouraging the farther away from the anus the tumor is situated. Malignant disease of the pylorus can often be recognized quite early through the ischochromia which it usually produces. In these instances a laparotomy should be performed as soon as possible and the pylorus resected, with establishment of a new communication between stomach and duodenum if possible; if not, a gastroenterostomy alone should be made. The latter operation is in many cases of decided benefit, facilitating nutrition and rendering the pains less.

Cancer of the lesser curvature of the stomach or of the posterior wall is usually recognized quite late, rendering radical operations practically impossible. If cardia and pylorus are not involved, there will be no need of operation, and the usual palliative remedies should be administered. The same may be said also of cancer of other portions of the stomach not involving either cardia or pylorus, in which a radical operation does not appear possible.

Cancer of the rectum can be recognized at an early stage, and resection of the neoplasm is here accompanied by brilliant results. If the tumor is located farther up in the large bowel or the small intestine, the results of an operation are not so promising, for here the recognition of the growth is possible only at an advanced period, and by that time adhesions with other organs and cancerous infection of the glands have already taken place.

Excision of the tumor and resection of the intestine in the neighborhood of the neoplasm, with an end-to-end anastomosis, should be practiced whenever feasible. In case, however, total resection is impossible, an enterostomy or enterocolostomy, or, if the
cancer is situated in the rectum, a colostomy (artificial anus), will be of benefit. These operations are palliative in nature and pro-long life, at the same time making it more comfortable. They are intended to allay the symptoms of obstruction and to carry the fecal matter over a new route, not passing through, and thus not irritating, the cancerous area. In some instances of inoperable cancer of the rectum curettage, followed by the application of the thermocautery, may be of benefit for a short time.

**RECURRENT SPONTANEOUS EPISTAXIS.**

**Natier (La Parole)** holds that by means of the mirror and specula commonly employed in the practice of rhinology the seat of bleeding from the nose can be accurately determined and effectively treated, reporting in detail a number of cases as proof of this contention.

The hemorrhage always takes place from the septum, and by predilection from the cartilaginous septum, about four-fifths of an inch behind the free border and an equal distance from the floor of the nose. The seat of epistaxis can often be perceived by lifting the tip of the nose and allowing light to fall in without the use of the speculum. It is rarely bilateral. It is often persistent, recurring without treatment for many years.

The immediate treatment of these cases consists in packing with antiseptic cotton or gauze. The curative treatment, designed to prevent recurrence, consists in transformation of the ulcerated and friable mucous membrane from which the blood flows into cicatricial tissue. This is accomplished by cautery. The author prefers the galvanocautery, the region having previously been anesthetized with cocaine.

**RESECTION OF NEARLY TWO METERS OF SMALL INTESTINE, AND ITS EFFECT ON DIGESTION.**

Carl Schlatter (Correspondens Blatt f. Schweizer Aerzte, July 15, 1899; quoted in the British Medical Journal, July, 1899) publishes the following case:

An Italian, aged twenty-three, was stabbed in the hypogastrium at 7 P.M. on October 9, 1898. He fell to the ground with intestine protruding from the wound, but with assistance walked some 300 meters to his home, where a provisional dressing was applied; he was brought in an ambulance to the Zurich clinic at 3 A.M. on October 10. About two meters of small intestine, the greater part deep blue or black in color, with quite dull serosa, was found protruding from the right hypogastrium; there was no collapse. Under ether (4 A.M.), when the skin and edges of the wound had been disinfected, it was found that the prolapsed intestine, jammed fast in the wound, was already partially necrotic; reposition was out of the question, and the only hope lay in total resection. Enough intestine was carefully drawn out to allow the operation to be performed through sound tissue. Wolfer's compressors were applied to each end, Péan's forceps closing the intermediate part and successively securing the mesentery as it was rapidly divided along its intestinal insertion. Union of the defect in the mesentery after the forceps had been replaced by ligatures was accomplished by separate silk sutures. The bowel was brought end to end by three rows of suture. The wound was then enlarged to permit reposition, when it was found that the constricting ring was formed by the slit in the skin, which lay three fingerbreadths above and parallel to Poupart's ligament; on the peritoneal side the wound was much larger.

As there was no effusion of blood into the peritoneum or sign of any opening into the bowel, the abdominal wound was closed by suture in tiers. The resected gut was 192 centimeters in length unstretched, and was entirely from the ileum. Except for an attack of urticaria there was hardly any reaction. On November 3 the patient was feeling quite well, on full diet, and weighed 64 kilos; on December 7 he was discharged, weighing 75 kilos, looking well, with a good appetite, and almost daily stool. Careful observation of the assimilation of albuminoids and fat was carried out for nine days; the patient was left entirely free in his choice of the kind and amount of the ordinary food of the hospital, and consumed a surprising quantity of nitrogenous and fatty matter. The loss of nitrogen was on the average 10.47 per cent, about the extreme normal loss, but the loss of fat was increased, being on the average 13.91 per cent, with variations from 9.47 to 20.26 per cent. In Fantino's patient, from whom 310 centimeters of ileum was removed when he was sixty years old, the loss of nitrogen was on the average twenty-nine per cent, that of fat as much as twenty-three per cent, varying from 17.2 to 34.3, but in spite of deficient assimilation wasting was avoided by overfeeding. Dreesman collected twenty-six cases (including his own patient) of resection
of more than one meter of the small intestine; seventeen survived the operation, five of whom suffered from digestive troubles; in all the other twelve the digestive functions were uninjured, but in ten the resected intestine measured less than two meters. There have been only six cases of the resection of more than two meters of the lesser bowel: 209 centimeters (Koebberle); 209 centimeters (Kocher); 215 centimeters ileum (Dreesman); 234 centimeters ileum (Shepherd); 310 centimeters ileum (Fantino); and the most extensive, 330 centimeters of small intestine (Ruggi) in a boy of eight for circumscribed peritonitis. Only two of these patients escaped with the digestive function unimpaired, namely, the first (209 centimeters) and the last (330 centimeters). Dreesman concluded that resections of less than two meters could be borne with impunity when there were no complications, but only young people could support a loss of greater length without the digestion being impaired.

AN EFFECTIVE TREATMENT OF VESICAL HEMORRHAGE WHEN CAUSED BY PAPILLOMATOUS GROWTHS.

HERRING (British Medical Journal, July 29, 1899), following the method practiced by Sir Henry Thompson, is able to report a number of cures by injection of silver nitrate solutions. The diagnosis of the cases was invariably confirmed by removing a portion of the tumor and submitting it to microscopic examination. Such specimens are usually obtained by washing out the bladder freely with warm sterile water, examining the debris brought away for shreds of tissue, and mounting them at once.

The instruments used are a soft, slightly elbowed catheter with the eye situated near the end, and a four-ounce india-rubber bottle furnished with a brass taper nozzle and stop-cock, together with a standard solution of one grain of nitrate of silver to one drachm of distilled water, acidulated with a small quantity of free nitric acid.

The injections are commenced by adding half a drachm of the standard solution to four ounces of warm water, and the strength is gradually increased every day or two until one or even sometimes two drachms has been added. The strength should be so regulated that no pain, increased frequency of micturition, or straining will follow the injection. Occasionally, when the maximum strength has been in daily use for a considerable time, the bladder becomes irritable, and the strength should be reduced, but the treatment should not be stopped.

As soon as the patient has learned to inject himself efficiently — throwing into the bladder half the contents of the bottle, retaining the solution for a few seconds and then letting it run off, and repeating the same process with the second half—he should do it daily; at night, perhaps, is the best time, for it is always advisable to rest afterwards. Before a patient can be trusted to make the injection himself, it is necessary to give him a few lessons in a uniform and systematic way of doing it, so as to insure perfect aseptic conditions, absence of injury or irritation to the organs, and the desired effect of the nitrate in the bladder. He should continue this without intermission for four, five, or six months, reaching his maximum strength of solution some five, six, or more weeks from the commencement of the treatment. If then bleeding has ceased, as it should have done, he may inject every other day for six months longer, and afterwards every third day for a variable period. A patient having been subjected to this long course of treatment may discontinue the application, even for a year, without any symptoms recurring; but he should return to daily injections—commencing with the minimum strength and gradually increasing—immediately blood reappears in the urine. In this way hematuria, and also the growth, may be permanently controlled, and the patient may live in comfort for many years.

The treatment at the start may occasionally increase the hemorrhage, but after several applications the blood lessens in quantity and finally disappears. In a few cases it never entirely ceases throughout the treatment, and is especially noticeable in small quantities at the time of catheterization, though every precaution may have been taken to introduce the instrument with care. It is apparently caused by the catheter damaging a growth situated near the neck of the bladder. In such a case, when the treatment is discontinued the hemorrhage ceases, and the after-effect may be quite satisfactory.

During the treatment shreds of tumor may often be found in the urine, differing very much from the characteristic papilloma. To the unaided eye the firm, pinkish, semitransparent tissue, composed of numerous rounded villi, has given place to a soft, white, opaque, and irregular mass. Microscopically the dis-
tinct villi, composed of easily distinguished translucent cells, arranged in irregular layers around the central blood-vessels filled with corpuscles, have disappeared, and it is difficult to make out either villi or cells; the cell substance is cloudy and granular, and the blood-vessels have shrunk, effects produced doubtless by the continued local applications.

SOME EXPERIMENTS ON THE CURE OF ANTHRAX.

Smith and Gunn (Australasian Medical Gazette, Aug. 21, 1899) prove experimentally that sheep can be cured eight hours after the injection of a dose of virulent anthrax sufficient under ordinary circumstances to kill the animal within thirty hours. It follows that if one of the animals more susceptible to this disease can be so successfully treated, we have every reason to believe that said treatment for virulent cases of anthrax in man can be equally successful if injected around the seat of infection of wound anthrax, while in cases of general anthrax or in woolsorters' disease the injection of excessive quantities would materially increase the chances of recovery of a patient.

By an immune sheep the experimenters mean one that has been vaccinated against anthrax, and the immunity of which has been subsequently proven by its perfect resistance to the injection of the virulent germ. Minimum doses required for sheep are 40 cubic centimeters if used four hours after the injection of 0.1 cubic centimeter of a cultivation of virulent anthrax, or 150 cubic centimeters if used six hours afterward, and 250 cubic centimeters if used eight hours afterward.

If the initial dose is too small, future injections are of little value. The injection of large quantities of the serum appears to have no ill effect upon the animal.

KERNIG'S SIGN IN MENINGITIS.

Herrick (American Journal of the Medical Sciences, July, 1899) thus describes Kernig's sign: If a patient with meningitis be made to sit up, as on the edge of the bed, the thigh therefore being at a right angle with the body, it is found extremely difficult to extend the leg because of the presence of a marked flexor contracture. To quote Kernig: "The phenomenon is so striking, the difference between nothing and something ('zwischen null und etwas'), between the complete absence of the contracture while the patient is lying down and its presence when the patient sits up, is so plainly perceptible, that it is well worth while to pay especial attention to this symptom and to examine for it in every case."

Kernig saw fifteen cases of meningitis, in all of which he found the symptom. In eight cases there was confirmation of the diagnosis by autopsy. Of the fifteen cases, thirteen were epidemic cerebrospinal meningitis, one tuberculous, one suppurative. Kernig failed to find the sign in many diseases other than meningal affections. In six cases, however, where there was not acute meningitis, the sign was more or less marked; yet in all these he found some pial trouble—edema, intracerebral hemorrhage, circumscribed meningitis, chronic meningitis, general carcinosis. Kernig believes the sign appears in meningitis as early as the rigidity of the neck, and that it is late to disappear.

From the study of cases made by Kernig, Bull, Henoch, Fris, Blumm, and Netter, with the observations recorded by Herrick, it seems justifiable to regard Kernig's phenomenon as present in the majority of cases of meningitis—say eighty to ninety per cent—and as only exceptionally present in other affections. Other and more definite conclusions concerning it seem unwarranted at present. That it may occasionally be absent in meningitis and occasionally present in diseases other than meningitis should not cause it to be wholly discarded as of no value. The truly pathognomonic symptoms are few. Rose spots in typhoid, herpes in malaria and pneumonia, absence of free hydrochloric acid in carcinoma of the stomach, murmurs in endocarditis, choked disk in cerebral tumor, and scores of other symptoms, are not pathognomonic, but rightly deserve attention, when found or when absent, as helping to make up or modify the symptom-complex of a disease, the method of diagnosis upon which as yet clinicians are compelled largely to rely.

As to the technique of eliciting this sign, it is exceedingly simple. The patient may be made to sit up on the edge of the bed with the legs hanging down, thus bringing the thighs at right angles to the body, when extension of the leg can be attempted; or the thigh can be brought at right angles to the body as the patient lies in bed on the side, or preferably on the back, and the leg then extended. The only requirement seems to be that the thigh should be placed at a right angle with the body before the attempt is
made to extend the leg. Not infrequently in delirious patients—e.g., in delirium tremens—a little patient, gentle force must be used before the jerking and tense muscles yield. The same is true of some spastic conditions. But where Kernig's contracture is present patience and gentleness do not cause the muscles to yield, and the back of the patient can generally be lifted from the bed without the knees giving way. This procedure is often accompanied by evident pain to the patient. In some cases the leg and thigh will make an obtuse angle of no more than 110° or 120°. As Kernig says, the test in many cases is most striking, particularly in those patients where thigh and leg in the recumbent position are extended and apparently lifeless, but in the test position reveal a most intensely rigid contracture, often with evidence of acute pain. In testing for Kernig's sign there must be excluded those cases in which local causes could interfere with the proper extension of the leg, such as rheumatic or other form of arthritis of the hip or knee, myositis, old contractures from nervous diseases, and sciatica. The phenomenon can be well imitated by the latter condition.

OPERATION FOR PERFORATION IN TYPHOID FEVER.

Ryan (Australasian Medical Gazette) operated on a farmer thirty-eight years old, who had been ill in bed with typhoid fever for eight days. The patient suddenly experienced agonizing abdominal pain, followed by a drop in temperature to 98.2° F., shortly rising to 100.8° F. The abdomen rapidly became distended. He was operated on two and one-half hours from the onset of the pain. There were flacks of lymph adherent to the intestines, and the pelvis contained about a pint of offensive fluid. A small opening was found eighteen inches from the cæcum, which was closed, and the whole of the pelvis and abdominal cavity was thoroughly irrigated with hot sterilized water. The wound was closed without drainage. The patient died in thirty-six hours of septic pneumonia, due to inspiration of vomited matter.

A CASE OF Puerperal Septicemia Treated with Antistreptococccic Serum.

Hamilton (Australasian Medical Gazette, Aug. 21, 1899) calls attention to the fact that the use of antistreptococccic serum in no way dispenses with the necessity for local treatment, as probably in all cases of puerperal septicemia there is a mixed infection, and other organisms beside the streptococcus pyogenes are present in the uterus and capable of causing a fatal toxemia if their growth is not prevented.

In her first attack this patient was treated by curettage and irrigation with antiseptic solutions. She was confined to the hospital for nine weeks, but finally recovered. Two years later she had a similar attack of about the same severity. The treatment practically was the same as before, except that eighty cubic centimeters of the Pasteur antistreptococccic serum was injected. Each injection of serum was marked by a decided fall in temperature and pulse. This last attack confined her to her bed for three weeks and was not attended by complications.

The author states he has used this serum in two or three other cases, but never with such marked effect as with this particular patient.

Reviews.

General Pathology. By Dr. Ernst Ziegler. Translated from the Ninth Revised Edition, and Edited by Dr. Albert H. Buck.

The title-page and author's preface of this volume are somewhat puzzling. On the title-page it is noted that the book is published in 1899, yet Dr. R. Mead Bolton is named as one of the translators and as living in Philadelphia, although he has been away from this city for several years, and we believe he is not present teaching in St. Louis. Further than this, the date of the author's preface of the ninth German-edition is November, 1897, almost two years back.

Ziegler's Pathology is a too well known book to make a review necessary. It has been and will continue to be one of the standard works upon this important subject, and while, so far as we understand it, neither the translators nor the editor have attempted to alter or add to the text, the work has been done so well that none of the disadvantages of a translation are manifest in the volume before us. Taking it all in all, the illustrations are also good for a book of this character, although we think they might be better. Figure 393, which is meant to show a gelatin plate containing colonies of small bacilli, is practically entirely useless in the copy which is before us. It is in the text
that we find the chief value of the work, and those who know Ziegler’s Pathology appreciate its value, while those who do not ought to show their appreciation by buying it, thereby obtaining a large amount of most useful information.

Dr. Hughes’s book on practice is a small octavo of a little over 600 pages, bound in a good flexible cover and printed in rather small type, which however is of a character which can be easily read. The fact that it has reached the sixth edition within comparatively a few years after it was published shows that it has proved itself a useful and competent manual, and an examination of the pages of this sixth edition shows why this success is present. Its success depends upon the fact that it is concise, yet not so abbreviated as to leave out important material; that each edition has been well brought up to date—in other words, that it has been really revised by the author; and finally, while the author takes care in many instances to show that the statements are made by others, the book embodies in certain instances his own personal experience, which lends an added charm to the compilation. We do not know of any small book upon practice which we can so highly recommend as this one, and we do not doubt that its popularity will continue.

This, the third, volume of Progressive Medicine deals with Diseases of the Thorax and its Viscera, including the Heart, Lungs, and Blood-vessels; Diseases of the Skin; Diseases of the Nervous System; and Obstetrics. That upon diseases of the thorax is by Dr. William Ewart, of London, whose article shows that he has made careful research in the literature of medicine during the past year, and has culled from it what he believes to be the most useful practical points which can be utilized by his fellow practitioners. Indeed, we think that the practical character of his article is its chief value, and surely any one who reads it will see, as we have seen, that he has touched upon all the themes which the title of his paper covers.

To the general practitioner the article upon the skin by Dr. Steiwagon may not possess the interest that that of Dr. Ewart possesses; nevertheless, there are many points in which it will prove of value to the active physician, and at the same time it is an able résumé of dermatological literature of the past year, prepared by one who in virtue of large experience and long practice is thoroughly qualified to sift the useless from the useful.

The article upon nervous diseases, by Dr. Spiller, is typical of its author, in that it is thorough, carefully prepared, and accurate. Another department which will prove of very great interest to the general practitioner is that upon obstetrics, by Dr. Richard C. Norris, which is one of the best which has been contributed to Progressive Medicine since this work was begun. Not only does it mirror the present status of obstetrics, but it brings home to each practitioner the points which he needs for attending his parturient and puerperal patients.

Once more this manual of our medical student days appears in a new dress, thoroughly revised and somewhat enlarged by competent hands. At least one of the earlier editions, the thirteenth, was published by the well known house of Blakiston, but the fifteenth appears under the imprint of William Wood & Company.

The copious illustrations, many of which are colored, have always been one of the valuable principles of this singularly successful manual. Other manuals on physiology may come and go, but Kirke’s “goes on forever,” and its intrinsic merit must be extraordinary that it can survive through all these years the competition of more youthful rivals. The cause of this survival largely depends upon the skilful way with which each revision has been prepared.

Dr. Hall, who is a graduate both in philosophy and medicine at the University of Leipsic, and who was at one time a student of Carl Ludwig, one of the immortals in
physiology, has prepared this work in a manner highly characteristic of the science of physiology as it exists to-day and of the training which he has received. In some respects the present volume differs from any other book on physiology with which we are acquainted, although the more recent publications on this science have been approaching nearer and nearer to the scheme or plan followed by Dr. Hall. His first chapter is one concerning the physiology of the cell, or cytology, and it is unnecessary for us to state that in the present and future this subject must be of absorbing interest to the physiologist, since it deals so intimately with life. The second chapter is upon the physiology of contractile and irritable tissues. This chapter is of very great interest and is very well written, dealing as it does with the very important changes in the tissues which take place under the circumstances we have named. After this, in Part 2, come chapters in special physiology, including nutrition, the motor sensory activities, and reproduction, and including under nutrition the study of the physiology of the circulation, respiration, digestion, absorption, metabolism, and excretion. Then follow chapters dealing with the skin, the nervous system, the muscular system, and finally chapter 13 deals with reproduction.

One of the things which strike us most forcibly in reading these pages is that while the author has necessarily used a large amount of information from other books, the work is emphatically written by Dr. Hall, and we feel as if he were actually giving us information himself, rather than giving the words of others; and further, one feels confident, not only from the knowledge of his ability as a physiologist, but also from the character of the statements made, that these are physiological facts, and therefore can be put away in one's mind as being worthy of credence. We do not know how well the book will suit undergraduate students in medicine in the early years of their study, but certainly, to the student who is in a few months to go up for his final examination in physiology, the book can be cordially recommended, and it is one which all teachers of physiology should possess and carefully read. It is not often that a book which does not deal with practical things in medicine appeals to us in the way in which this one has done. It is one of the books which are placed at our right hand for careful further study and reference.

THE NERVOUS SYSTEM AND ITS CONSTITUENT NEURONES. By Lewellys F. Barker, M.D. Illustrated with Colored Plates and Engravings.

This large octavo volume of over 1100 pages is a monument to the learning and industry of Dr. Barker. In it he has presented the rich results of the more recent studies which have been made into the minute anatomy of the central and peripheral nervous system, and has embodied, in an invaluable manner, the present literature of this important subject, arranging it so consecutively that we pass from chapter to chapter by a series of steps in knowledge which are easily taken because of his lucid manner of writing.

Almost every page contains foot-notes referring to valuable monographs and essays, and in many instances these foot-notes are accompanied by a few words of criticism or explanation, written by the author, which add materially to their value, aside from their being bibliographical references. It should be distinctly understood that this book does not attempt to be a treatise upon diseases of the nervous system; it is emphatically a contribution of the skilled anatomist, who has devoted much time and original work to the elucidation of conflicting theories and the opening up of new fields in modern neurology.

It is to be regretted that all the illustrations are not equally good, though as a rule the faulty ones are those taken from other authors. To those who desire to become thoroughly in touch with the modern views concerning the anatomy of the nervous system in its relation to diagnosis and disease, this book can be recommended with the greatest possible enthusiasm. It is such contributions to the medical literature in this country which will raise our standard in the scientific world abroad better than any other effort we can make save in true original research.

ON THE ROLE OF INSECTS, ARACHNIDS, MYRIAPODS AS CARRIERS IN THE SPREAD OF BACTERIAL AND PARASITIC DISEASES IN MAN AND ANIMALS. A Critical and Historical Study. By George H. F. Nuttall, M.D., Ph.D.

Baltimore: Johns Hopkins Press, 1899.

This is an essay of over 150 pages devoted to the theme named in its title, and as its title indicates it discusses all those bacterial and parasitic diseases which have been studied by this and preceding investigators, taking up such important diseases on the one hand as
yellow fever and cholera amongst human beings, and on the other hand Texas fever and "Tsetse Fly Disease" amongst animals. A large number of its pages are devoted to the consideration of the "mosquito malarial theory," with which the readers of the Therapeutic Gazette are familiar in part by reason of a paper which has been recently published in our columns.

As may be known to some of our readers, Dr. Nuttall has for a number of years been living in Berlin, where he has been a volunteer assistant in the Hygienic Institute, and prior to this he was associate professor in Johns Hopkins University.

An examination of the pages of this brochure shows that Dr. Nuttall has exhausted the literature on the subject, and has presented us with a review of the greatest possible value, not only because of its own worth but also because it appears at a most opportune moment. The volume closes with a copious bibliography of over 350 references.

This is a large octavo of nearly 500 pages, designed as a dissecting manual for Morris's Human Anatomy. In other words, it is Morris's Human Anatomy boiled down, and the boiling down has been very well done. The cuts which illustrate it are mostly taken from Morris's well known work, and therefore it is unnecessary to say anything in regard to their quality, for everyone knows how singularly clear and useful they are. The general typographical appearance of the volume is quite identical with that of Morris's book, and to those students who use this Anatomy we believe that this vide-mecum will prove very useful. It certainly can be cordially recommended to students and to those practitioners who wish to brush up their anatomical knowledge, and what practitioner of some years does not need to do this?

Handy Book of Medical Progress. By Charles Warrenne Allen, M.D., and Jacob Sobel, A.B., M.D.

We confess we are at a loss to understand exactly what function this book is meant to fulfill. It may be described as a sort of small medical dictionary in large type. The various terms are alphabetically arranged, and a definition is given after them; for instance, we learn that Alpha-Eigon is an iodine compound of albumin, twenty per cent, and Alphasol is a proprietary preparation used as an antiseptic for gargles, nasal douches, sprays, etc.; and so on through the book short, abbreviated definitions of various terms are given, not only in connection with drugs but in regard to the names of tests and diseases. To any one who possesses even a small medical dictionary we do not think this book will be of value.

Asthma: Recent Developments in its Treatment.
By Ernest Kingscote, M.D., C.M. Illustrated.

The title of this book does not give a very correct idea of its contents. One would imagine that it dealt entirely with asthma, but as a matter of fact a very considerable portion of its pages deals with disorders of the heart, both functional and organic. It is a monograph prepared by the author, evidently to exploit certain views which he holds in regard to asthma in its relation to circulatory and respiratory conditions, and it closes with a page devoted to "Don'ts in connection with heart disease" and with a "l'envoi," in which the author naively tells us that he does not expect his readers, should there be any, to accept these theories on the subject, though he most fully believes in them, and by a still more naive statement on the last page that the literature of asthma can be found in the Index Catalogue in the Surgeon-General's office.

We have already reviewed in earlier issues of the Therapeutic Gazette the first three portfolios of this very useful atlas of skin diseases. We do not know when we have seen one, in which the illustrations were so good, which could be had at so moderate a price. The colored illustrations are unusually lifelike, and are made by the Photogravure Company of New York.

There is scarcely any department of medical illustration which is so difficult as that of skin diseases, since slight variations in the color entirely change the appearance of the picture. In these the coloring has been unusually well done. Not only is it true that the illustrations are first-rate, but the text is equally valuable, and it is of great value to the physician to find a clear typical picture of a given disease, facing a page upon which careful directions are given for its treatment,
to which directions are added for typical prescriptions which will be found useful in such conditions.

The publication is one which, either in the form of separate portfolios or in a bound volume, which will ultimately be issued when the folios are completed, can be possessed with advantage by any general practitioner or specialist in skin diseases.

This small octavo volume of nearly 400 pages belongs to Lea’s series of text-books, with many of which the profession is already familiar. It is emphatically a compilation or result of “boiling down” information obtained from larger and standard works, and in the preface we learn that the largest amount of information has been abstracted from the well known treatise of Dr. Holt, of New York, upon Pediatrics.

The various chapters in the book deal with the healthy infant and feeding in infancy; the diseases which are met with in infancy as they affect various portions of the body; and finally there are closing chapters upon Infectious Diseases.

To the student who desires to prepare himself for an examination in the branch of diseases of children, and who has not time to take up and read with care the more extensive text-books, this one can be cordially recommended.

MINOR SURGERY AND BANDAGING. Including the Treatment of Fractures and Dislocations, the Ligation of Arteries, Amputations, Excisions and Resections, Intestinal Anastomosis, Operations upon Nerves and Tendons, Tracheotomy, Intubation of the Larynx, etc. By Henry R. Wharton, M.D. Fourth Edition, Thoroughly Revised and Enlarged, with 502 Illustrations.

The favorable reception accorded to Wharton’s three previous editions of this book, and the universally commendatory reviews which have appeared in this and practically all journals, instance no more clearly than does this fourth edition of his work the admirable manner in which the art of minor surgery and bandaging has been set forth. The illustrations are particularly well chosen, since in practically all cases they are supplementary to the text, making it more readily understood. The Section upon Surgical Bacteriology, and the Preparation of Materials used in Aseptic Operations, will prove most useful, because of the clearness of the teaching and the orderly manner in which it is set forth. The chapter upon Anesthesia, founded as it is upon a wide experience, should be carefully studied. The addition of articles upon Tracheotomy, Intubation of the Larynx, Ligation of Arteries and Amputations, Resections, Operations upon the Kidney, the Colon, and the Bladder, Gastrostomy, etc., distinctly increases the value of the work, especially to medical students.

A COMPEND OF GYNECOLOGY. By William H. Wells, M.D. With Illustrations. Quiz Compend No. 7.

This second edition of Wells’s Quiz Compend on Gynecology includes the many excellent features of the first edition, together with a much fuller consideration of the field of operative gynecology. Whatever may be the merits and defects of these small books upon special subjects arranged for the use of students, and particularly, sometimes solely, for the purpose of helping them successfully to pass their examinations, it is evident from the popularity which the best of them have attained that they have proven useful not only to the student but to the general practitioner of medicine. This book of Wells’s contains all the good points to be found in works so condensed. It is direct and fairly comprehensive, and as such is to be warmly commended.

Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFURD, M.A., M.D. OXON., M.R.C.P. LOND.

In a recent letter I spoke of the expedition recently sent out by the Liverpool School of Tropical Medicine to investigate the causation of malaria. Their labors have so far met with the utmost success, as may be gathered from the following letter of Mr. Ronald Ross: “We have now practically finished our work here. We have found: (a) that local species of Anopheles (mosquitoes) carry malaria; (b) that these species breed in a few stagnant puddles. These observations support my inaugural lecture at every point. Needless to say we have been most exceptionally lucky to have done so much in so short a time. We shall, of course, wind up with a scientific report to the committee. The practical results to be derived from the
facts which we have obtained will depend solely on the government and the medical profession here. Fortunately, Major Nathan is taking great interest in our work, and so are the colonial doctors. Of course, we could kill most of the Anopheles grubs here in a few hours with kerosene oil, and the thing will be done shortly after Ould arrives. But this won't be enough. It is necessary that the operations be continued systematically, and that some of the most dangerous puddles be drained (costing a trifle). Consequently the Governor asked us to advise. I suggested that one of his medical officers be put in charge of the operations against the mosquito, and that he be given a trustworthy native assistant. The proposal is before the Governor. For many scientific reasons we have come to the conclusion that the truly malarial fever is solely caused by the mosquito—probably entirely by the Anopheles species. We estimate that most of the malarial fever here can be got rid of at almost no cost, except of a little energy on the part of the local authorities. I am having a look round at the other medical and sanitary matters—drainage, conservancy, etc. You will understand, of course, that it will take some time for the public to get the mosquito theory into their heads, but it will come in time. Many thanks for sending Ould. I propose to show him what to do here, and then send him down the coast. It has been quite impossible for us to go over to Accra. We should have had to start a week ago if we wished to catch the Fantee on her return. This would have broken off our work here at the most important point. Dr. Strachan, chief medical officer of Lagos, is hard at work on Anopheles there, and you may be sure that the alarm will be raised all down the coast before long. Ould can show them how to hunt up the puddles. Dr. Van Neck has arrived here.—Yours sincerely, R. Ross." (Reuter.)

Those who take an interest in the detailed work of the expedition should read an admirably lucid letter from a correspondent at Sierra Leone in the *British Medical Journal* of September 30, entitled "Anopheles and its Habits; Malarious Foci Localized."

It is to be hoped that similar success may attend the efforts of the workers in the pathological laboratory of the Malay Peninsula in their investigation into the causes of beriberi. A meed of praise for this work is due not only to the scientific experts, but even more so to the exemplary Colonial Secretary, who has made these investigations practicable.

I would call attention to a very practical article on the "Local Treatment of Puerperal Infection," in which Dr. Arnold Lea analyzes forty-eight cases that had come under his own notice. The details of these cases may be studied in the August number of the *Medical Chronicle*, but it may not be out of place to state briefly the conclusions he derives from these cases: (1) That a rise of temperature above 101.4° occurring during the puerperium without obvious assignable cause should lead to a thorough examination of the genital passages. (2) That if the examination of perineum and vagina gives a negative result, a uterine douche should be given with proper precautions. The various accidents that have attended the employment of the uterine douche may be reduced to a minimum by using only a mild antiseptic and injecting it slowly and without pressure. (3) If within twenty-four hours the temperature has fallen definitely, no further exploration is required, but the douche may be repeated if the temperature again rises. The uterine douche practically can cope with sepsis, the source of which lies in the decomposition of lochia or blood-clots, but not with the products of conception retained in utero. (4) If at the end of twenty-four hours the temperature is higher, and the pulse-rate has increased, the cavity of the uterus should be explored with the sterilized finger. (5) If the initial rise of temperature is great (103° or over), with or without a rigor, the uterus should be explored at once, not waiting twenty-four hours to observe the effect of a douche. This is more especially indicated if the uterus is bulky, showing delayed involution, since this points to putrefaction of retained products, or to septic endometritis. (6) If clots or placenta are discovered, they should be removed by the finger or curette, a douche given, and a gauze drain inserted for twenty-four hours. (7) In the great majority of cases it is wiser to thoroughly curette the uterus with the object of removing the whole of the decidua and retained products. (8) There is no evidence that curettage, if done with every precaution, favors the spread of infection. In a large proportion of cases the infection is rapidly checked. (9) In very virulent infection early curettage with the object of sterilizing the uterine cavity affords the best chance of a successful result. (10) If curettage entirely fails, it must be repeated or not, according to the local condition present.
The prognosis, however, in the absence of a definite localization of the infective process is bad. (11) In some cases, if curettage fails, and there is no evidence of general peritonitis or of infection of the blood-stream, vaginal hysterectomy, if performed in good time, may be successful. So far as Dr. Lea's statistics go the benefit of this extremely radical procedure seems to be merely a pious expression of opinion, for it was tried but once and then was ineffectual to prevent death. (12) Antistreptococcic serum should be given early and freely in cases of proved streptococcic infection. It is of little use in the advanced stages of the disease.

Schäfer and Swale Vincent have just completed an interesting series of observations on the physiological effects of extracts of the pituitary body. A full account of their observations may be read in the September number of the Journal of Physiology. They find that pituitary extracts when injected into the venous circulation may produce either a marked rise or marked fall of blood-pressure, varying with the nature of the extract. In other words, it contains two active principles, which may be conveniently termed pressor and depressor, to emphasize the contrary effects they produce. The pressor substance is soluble in salt solution and insoluble in absolute alcohol and ether; the depressor substance is soluble in salt solution, in absolute alcohol, and in ether. Neither of the active principles is destroyed by boiling, and each is dialyzable. They confirm Schäfer and Oliver's previous observations that the pressor substance produces its action both upon the heart and peripheral arteries, and that its action is a prolonged one, and Howell's observation that during the period of its action a second dose is inactive or nearly so. On the other hand, the action of the depressor substance is evanescent and can be repeated at short intervals. They find also that the rise of blood-pressure due to the pressor substance may be accompanied by slowing of the heart; this they attribute mainly to the contraction of arterioles and rise of aortic pressure, but in part also to direct action upon the peripheral cardiac mechanism. They also confirm Howell's finding, that the active substances are contained only in the infundibular and not in the hypophysial part of the pituitary body. Subcutaneous injection of the extracts in small animals caused paralytic symptoms similar to those obtained by injecting suprarenal extracts. They also confirm Howell's observation that the characteristic effects are not due to the gray nervous matter of which the infundibular portion is largely composed. It seemed likely that the fall of blood-pressure was due to choline in the extract, which is a known derivative of gray nervous substance; but that this was not the case was shown by the fact that the fall was not affected by administration of atropine, which directly antagonizes the action of choline. They conclude that the depressor action of choline is exerted through the cardio-inhibitory mechanism, whereas that of pituitary extract is a peripheral action upon the musculature of the vascular system.

At the recent meeting of the British Medical Association Dr. Hinshelwood, of Glasgow, made an important communication on the use of euphalmicine as a mydriatic. He uses a five-per-cent aqueous solution of euphalmicine, and finds its rapidity in dilating the pupil almost equal to that of a one-per-cent solution of homatropine; but by previously instilling into the eye a single drop of a one-per-cent solution of cocaine, the euphalmicine solution acts quite as rapidly as homatropine, producing a maximum dilatation of the pupil in about twenty minutes. Moreover, the dilatation of the pupil produced by euphalmicine passes off more readily than that produced by homatropine. Dr. Hinshelwood has also established the point that has been contested by some ophthalmologists, that euphalmicine has some slight paralyzing effect on accommodation; but in this lies its great merit in practical usefulness, that the paresis of accommodation passes away completely in from an hour and a half to two hours from its first instillation. Euphalmicine causes no smarting and no discomfort of the eyeballs; it has no apparent effect on the conjunctival vessels or corneal epithelium; it does not raise the tension of the eye, and produces no toxic effects.

In connection with the pathological laboratory in Malay for the investigation of beriberi, to which I alluded in the earlier part of this letter, it may interest you to learn that Dr. Hamilton Wright, formerly pathologist to the Royal Victoria Hospital, Montreal, will be director. The Government of the Straits Settlement has announced that it will be glad to assist research scholars who take part in the investigation by providing them with furnished quarters, rent free, by giving them the free run of the hospitals and laboratory, by defraying the cost of passage to the Colony, and in such other ways as may
meet the needs of individual cases. I presume the invitation is extended to Americans as much as to Englishmen.

PARIS LETTER.

BY A. R. TURNER, M.D. (PARIS).

At the Congress of Obstetrics and Gynaecology held at Amsterdam from August 8 to 12, the celebrated French accoucheur, Professor Pinard, compared the value of the three operations for contracted pelvis—symphyseotomy, Cæsarian section, and craniotomy. Dr. Pinard said that Cæsarian section was certainly theoretically an ideal operation, hemorrhage and infection having been reduced to a minimum. The speaker then analyzed the statistics of Olshausen, Leopold, and Zweifel, which are as follows:

Olshausen: 29 operations, 27 recoveries, 2 deaths; 3 infants died.
Leopold: 100 operations, 90 recoveries, 10 deaths; 13 infants died.
Zweifel: 55 operations, 1 death.

Leopold has laid down the conditions necessary for undertaking this operation with success. The woman should have energetic contractions, and she should be in good health; there must be no trace of infection, gonorrhœa or otherwise; and lastly, the bag of waters should be intact. When all these do not exist, Leopold has recommended either Porro’s operation or basiotompy. The same applies to cases where asepsis cannot be guaranteed.

Dr. Pinard added that the foregoing results were those obtained by very experienced operators, where they were able to operate on certain selected cases. He then went on to give the results of symphyseotomy such as it has been done since 1893 at the Clinique Baudelocque. From February 4, 1892, to January 20, 1899, a hundred symphyseotomies had been performed by Varnier, Potocki, Lepage, Wallich, Bouffe de St. Blaisé, Baudron, Funck-Brentano, and Dr. Pinard. There had been in all twelve deaths, and from this number should be subtracted the following cases: intestinal obstruction, infectious influenza, pneumonia, eclampsia, and three cases of infection having no connection with the operation. The mortality in all cases was therefore only five per cent. Thirteen children died, and seven cases were due to applications of forceps before symphyseotomy, to an incomplete symphyseotomy, and to accidental bronchial pneumonia, which would make six per cent. An important point in Dr. Pinard’s communication was that twenty-two women already symphyseotomized came into the service a second time. In only six cases was a second symphyseotomy found necessary.

From 1882 to 1899 craniotomy was performed eighty-one times in Dr. Pinard’s service at the Clinique Baudelocque, or at the Lariboisière Hospital, and the mortality was 11.5 per cent.

Lastly, premature birth was induced in one hundred cases, and there was only one death. As for the children, only sixty-seven survived.

Dr. Pinard concluded his report by saying that he considered an accoucheur should be primarily a physician, and therefore do all he can to safeguard the lives of both mother and child. He denounced induced labor on account of its heavy infantile mortality; on the other hand he did not believe it right to discuss the relative value of the mother’s life or the child’s. Moreover, a physician should prefer a relatively complicated operation with a sure result to an easy one with a doubtful result. Dr. Pinard said the degree of contraction of the pelvis is not of so much importance as is the question of its relation to the dimensions of the child’s head. When the contraction is very considerable, Cæsarian section should be carried out. Above 6.5 centimeters symphyseotomy is, according to Dr. Pinard, the best operation, when the woman is not infected. As to what one should do when she is already infected, the experience acquired so far is not sufficient to justify one in deciding positively for one or the other operation.

Dr. Pinard concluded with the following words: “These things should be suppressed in the therapeutics of pelvic contraction: (1) Induced labor; (2) forceps or version when there is some osseous obstacle; (3) embriyotomy on a living child. During labor two things should be avoided: (1) Tëdious labor; (2) infection. The operations to be carried out are: (1) Symphyseotomy, pubiotomy, ischio-pubiotomy, coccygotomy; (2) Cæsarian section, with or without hysterectomy; (3) embriyotomy on a dead child.

In a recent number of the Belgian Medical Press Dr. Siegrist, of Zurich, described his method of treating an acute attack of sciatica. The patient is placed on his side so that the region affected is quite uncovered, and on the latter a cloth dipped in hot water (50° to 60° C.) and slightly wrung out is placed, and covered over with a piece of flannel and
of more than one meter of the small intestine; seventeen survived the operation, five of whom suffered from digestive troubles; in all the other twelve the digestive functions were uninjured, but in ten the resected intestine measured less than two meters. There have been only six cases of the resection of more than two meters of the lesser bowel: 205 centimeters (Koehler); 209 centimeters (Kocher); 215 centimeters ileum (Dreesman); 234 centimeters ileum (Shephard); 310 centimeters ileum (Fantiino); and the most extensive, 330 centimeters of small intestine (Ruggi) in a boy of eight for circumscribed peritonitis. Only two of these patients escaped with the digestive function unimpaired, namely, the first (205 centimeters) and the last (330 centimeters). Dreesman concluded that resections of less than two meters could be borne with impunity when there were no complications, but only young people could support a loss of greater length without the digestion being impaired.

AN EFFECTIVE TREATMENT OF VESICAL HEMORRHAGE WHEN CAUSED BY PAPILLOMATOUS GROWTHS.

HERRING (British Medical Journal, July 29, 1899), following the method practiced by Sir Henry Thompson, is able to report a number of cures by injection of silver nitrate solutions. The diagnosis of the cases was invariably confirmed by removing a portion of the tumor and submitting it to microscopic examination. Such specimens are usually obtained by washing out the bladder freely with warm sterile water, examining the débris brought away for shreds of tissue, and mounting them at once.

The instruments used are a soft, slightly elbowed catheter with the eye situated near the end, and a four-ounce india-rubber bottle furnished with a brass taper nozzle and stop-cock, together with a standard solution of one grain of nitrate of silver to one drachm of distilled water, acidulated with a small quantity of free nitric acid.

The injections are commenced by adding half a drachm of the standard solution to four ounces of warm water, and the strength is gradually increased every day or two until one or even sometimes two drachms has been added. The strength should be so regulated that no pain, increased frequency of micturition, or straining will follow the injection. Occasionally, when the maximum strength has been in daily use for a considerable time, the bladder becomes irritable, and the strength should be reduced, but the treatment should not be stopped.

As soon as the patient has learned to inject himself efficiently—throwing into the bladder half the contents of the bottle, retaining the solution for a few seconds and then letting it run off, and repeating the same process with the second half—he should do it daily; at night, perhaps, is the best time, for it is always advisable to rest afterwards. Before a patient can be trusted to make the injection himself, it is necessary to give him a few lessons in a uniform and systematic way of doing it, so as to insure perfect aseptic conditions, absence of injury or irritation to the organs, and the desired effect of the nitrate in the bladder. He should continue this without intermission for four, five, or six months, reaching his maximum strength of solution some five, six, or more weeks from the commencement of the treatment. If then bleeding has ceased, as it should have done, he may inject every other day for six months longer, and afterwards every third day for a variable period. A patient having been subjected to this long course of treatment may discontinue the application, even for a year, without any symptoms recurring; but he should return to daily injections—commencing with the minimum strength and gradually increasing—immediately blood reappears in the urine. In this way hematuria, and also the growth, may be permanently controlled, and the patient may live in comfort for many years.

The treatment at the start may occasionally increase the hemorrhage, but after several applications the blood lessens in quantity and finally disappears. In a few cases it never entirely ceases throughout the treatment, and is especially noticeable in small quantities at the time of catheterization, though every precaution may have been taken to introduce the instrument with care. It is apparently caused by the catheter damaging a growth situated near the neck of the bladder. In such a case, when the treatment is discontinued the hemorrhage ceases, and the after-effect may be quite satisfactory.

During the treatment shreds of tumor may often be found in the urine, differing very much from the characteristic papilloma. To the unaided eye the firm, pinkish, semitransparent tissue, composed of numerous rounded villi, has given place to a soft, white, opaque, and irregular mass. Microscopically the dis-
tinct villi, composed of easily distinguished translucent cells, arranged in irregular layers around the central blood-vessels filled with corpuscles, have disappeared, and it is difficult to make out either villi or cells; the cell substance is cloudy and granular, and the blood-vessels have shrunk, effects produced doubtless by the continued local applications.

SOME EXPERIMENTS ON THE CURE OF ANTHRAX.

Smith and Gunn (Australasian Medical Gazette, Aug. 21, 1899) prove experimentally that sheep can be cured eight hours after the injection of a dose of virulent anthrax sufficient under ordinary circumstances to kill the animal within thirty hours. It follows that if one of the animals more susceptible to this disease can be so successfully treated, we have every reason to believe that said treatment for virulent cases of anthrax in man can be equally successful if injected around the seat of infection of wound anthrax, while in cases of general anthrax or in wool-sorters' disease the injection of excessive quantities would materially increase the chances of recovery of a patient.

By an immune sheep the experimenters mean one that has been vaccinated against anthrax, and the immunity of which has been subsequently proven by its perfect resistance to the injection of the virulent germ. Minimum doses required for sheep are 40 cubic centimeters if used four hours after the injection of 0.1 cubic centimeter of a cultivation of virulent anthrax, or 150 cubic centimeters if used six hours afterward, and 250 cubic centimeters if used eight hours afterward.

If the initial dose is too small, future injections are of little value. The injection of large quantities of the serum appears to have no ill effect upon the animal.

KERNIG'S SIGN IN MENINGITIS.

Herrick (American Journal of the Medical Sciences, July, 1899) thus describes Kernig's sign: If a patient with meningitis be made to sit up, as on the edge of the bed, the thigh therefore being at a right angle with the body, it is found extremely difficult to extend the leg because of the presence of a marked flexor contracture. To quote Kernig: "The phenomenon is so striking, the difference between nothing and something ('zwischen null und etwas'), between the complete absence of the contracture while the patient is lying down and its presence when the patient sits up, is so plainly perceptible, that it is well worth while to pay especial attention to this symptom and to examine for it in every case."

Kernig saw fifteen cases of meningitis, in all of which he found the symptom. In eight cases there was confirmation of the diagnosis by autopsy. Of the fifteen cases, thirteen were epidemic cerebrospinal meningitis, one tuberculous, one supplicative. Kernig failed to find the sign in many diseases other than meningal affections. In six cases, however, where there was not acute meningitis, the sign was more or less marked; yet in all these he found some pial trouble—edema, intermeningeal hemorrhage, circumscribed meningitis, chronic meningitis, general carcinosis. Kernig believes the sign appears in meningitis as early as the rigidity of the neck, and that it is late to disappear.

From the study of cases made by Kernig, Bull, Henoch, Friis, Blümml, and Netter, with the observations recorded by Herrick, it seems justifiable to regard Kernig's phenomenon as present in the majority of cases of meningitis—say eighty to ninety per cent—and as only exceptionally present in other affections. Other and more definite conclusions concerning it seem unwarranted at present. That it may occasionally be absent in meningitis and occasionally present in diseases other than meningitis should not cause it to be wholly discarded as of no value. The truly pathognomonic symptoms are few. Rose spots in typhoid, herpes in malaria and pneumonia, absence of free hydrochloric acid in carcinoma of the stomach, murmurs in endocarditis, choked disk in cerebral tumor, and scores of other symptoms, are not pathognomonic, but rightly deserve attention, when found or when absent, as helping to make up or modify the symptom-complex of a disease, the method of diagnosis upon which as yet clinicians are compelled largely to rely.

As to the technique of eliciting this sign, it is exceedingly simple. The patient may be made to sit up on the edge of the bed with the legs hanging down, thus bringing the thighs at right angles to the body, when extension of the leg can be attempted; or the thigh can be brought at right angles to the body as the patient lies in bed on the side, or preferably on the back, and the leg then extended. The only requirement seems to be that the thigh should be placed at a right angle with the body before the attempt is
of these poisons in the body of the mother and in removing them before she has eclampsia. The comparative mortality of preventive treatment and of directly curative treatment in eclampsia has never been stated in absolute figures. Among women subjected to no care during pregnancy, recent observers estimate that one in eighty-five has eclampsia; others place the number at one to one hundred; still others consider eclampsia more frequent. It is most common in primiparæ, above the first years of child-bearing, and in patients with multiple pregnancy. The mortality in eclampsia is recently placed at twenty-four per cent; it varies from fifteen to twenty-five per cent in different statistics. The percentage of success obtained in preventing eclampsia may be estimated from the fact that during the last six years I have had under observation 1566 patients, each of whom was observed in a routine manner to determine the perfection of excretion. Of these patients, three had eclampsia. In neither case were convulsions severe, and in each mother and child recovered.

It is well first to consider in what way can be made the diagnosis of the accumulation of poisons commonly known as toxemia. It is generally thought that the examination of the urine is the most important factor in this diagnosis, and many regard it as the only examination necessary. This is, unfortunately, not correct, for some dangerous cases of eclampsia show little signs of approaching danger in altered urine. We can, however, obtain much valuable information from this source, and this examination is always an important one. We seek in this respect knowledge concerning two particulars: first, the presence or absence of solids; secondly, the presence or absence of kidney débris. Serum albumin is important only when in large amount and appearing with kidney débris. To estimate the solid waste, we ascertain the percentage of urea and compute the percentage of solids from the specific gravity of the urine, or make a special examination for this purpose. Urea is not in itself a poison, but indicates the perfection of the formation of solid waste in the body and its excretion. The percentage of urea may be conveniently and accurately estimated by any one of several forms of apparatus in the market. In my experience, Squibb's has served a useful purpose. To estimate the amount of solid matter in a given specimen of urine, one of several rules may be followed: the coefficient 2.33 may be used; and the last two figures of the specific gravity multiplied by this, which gives approximately the number of grammes of solid matter in one thousand cubic centimeters of urine. Haines’s method may be employed, which consists in multiplying the last two figures of the specific gravity of the urine by the number of ounces voided in twenty-four hours, and this product by 1.1. The difficulty in estimating accurately the amount of solid matter excreted in the urine arises largely in the fact that it is difficult to obtain an accurate record of the amount passed. An idea of the result desired which is fairly accurate is obtained from the specific gravity and the percentage of urea. In all doubtful cases the amount should be accurately measured.

The use of the centrifuge enables kidney débris to be recognized almost immediately and with little difficulty. We have in these two procedures—namely, the computation of solids and the recognition of kidney débris—the most important methods of diagnostating normal or abnormal excretion during pregnancy. Any well known method may be employed to detect the presence or absence of serum albumin. It must be remembered, however, that this substance is of clinical importance only when in excess and when accompanied by kidney débris.

While our examination of the urine may be conducted with reasonable scientific accuracy, the most important method of diagnosis in these cases consists in the clinical phenomena which the patient presents. Headache across the brow, melancholia, stupor, variations in appetite, lack of proper secretion in the skin, and constipation, are all symptoms recognized by a careful clinical observer without the employment of scientific apparatus. It is a frequent observation in my experience that many of the so-called disorders of early pregnancy characterized by the symptoms just described yield promptly to treatment addressed to stimulating the patient’s excretion. An appropriate diet, composed largely of milk, bread and butter, green vegetables and fruit, with an abundance of pure and soft water, is the first important prerequisite. The skin must be kept active by a warm tub-bath at night, and a cool sponge in the morning. Thin wool or silk and wool should cover the entire surface of the body from the neck to the feet. Abundant fresh air, the entire absence of all constriction of the abdominal viscera, and gentle exercise, such as walking at a leisurely pace
upon level ground, or light domestic work in well ventilated rooms, are all of importance.

The use of drugs in these cases should be adapted first to the maintenance of the regular action of the bowels, and secondly, to the promotion of the elimination of waste. If habitual but simple constipation be present, cascara may be used to advantage. A teaspoonful of aromatic cascara should be taken night and morning until the bowels move several times during twenty-four hours. The dose may then be lessened until at least one copious movement daily is secured. Few pregnant patients escape the impaction of feces, and should the slightest suspicion exist of this condition, a vigorous purge should be administered and cascara then employed. Two or three compound cathartic pills at night, followed by a saline and copious enema on the following morning, will partially clear the bowel. An agreeable saline each morning for a week following will assist in unloading the intestine, when the regular use of cascara will usually keep the bowels free. Should this means not be successful, lavage of the intestine should be practiced by a trained nurse. With the patient upon her left side, a soft rectal tube should be inserted as far as possible, and one ounce of ox-gall dissolved in one quart of warm soap-suds should be gently introduced into the bowel as high as possible. An hour after this, with the patient in the same posture, a copious irrigation of warm Castile soap-suds, or of warm water containing one ounce of magnesium sulphate to the pint, may be employed. By this means the large bowel can be efficiently emptied.

The treatment of simple constipation is rarely sufficient in these cases. It will be found that not only the intestine but the liver and kidneys are at fault. There is in my experience no drug so valuable as calomel in these patients, provided proper caution be exercised in its use. One-fourth grain of calomel with bicarbonate of soda may be given night and morning for several days, citrate of magnesia or other agreeable saline being employed on each following morning. The result of this administration is usually better than the giving of a single and larger dose. When, however, it is necessary to drain the intestine persistently to relieve the deficient action of the liver and kidneys, the compound colocynth pill of the Pharmacopoeia may be employed to advantage. From one to three of these pills taken at night result well.

It is possible to greatly increase excretion by the proper use of water. Pregnant patients, who suffer greatly from heartburn, find comfort in the free use of water charged with carbonic acid gas. The so-called sparkling saline waters agree well with these patients. Célestine Vichy, if taken cool, can usually be freely employed. If the patient does not wish to go to the expense of using an imported water, plain soda-water in which is dissolved one of the effervescent salts now upon the market may be employed to advantage. The potassium salts must be avoided in these cases, and other salines used instead.

The injurious effect of the alkaloids in common use has been frequently observed with these patients. Tea and coffee employed in excess greatly lessen the excretion of the pregnant woman. It is necessary in all cases where these substances have been habitually and excessively used to cut off their employment as soon as possible. Alcohol should not be taken by these patients in any form. The craving for tea or coffee may usually be appeased by the use of very hot water, effervescent drinks, and occasionally, for a short time, small doses of nux vomica or strychnine.

Success in the prevention of eclampsia is usually obtained under treatment which, while tedious at times to the patient, is rarely such as to interfere with her comfort. In fact, the prompt relief which she experiences from general malaise is most gratifying. In the presence, however, of eclamptic convulsions, when by the use of the remedies already described at the beginning of this paper we have temporarily subdued the fits, the very important question arises, What shall we do to prevent their recurrence?

It is commonly believed that the patient dies because of the eclamptic fits. If this is true, then the woman having the smallest number of fits should recover the most promptly. This is not the case, for some patients survive a comparatively large number of fits, while others perish after two or three. Our treatment must be addressed not so much to controlling the paroxysms as to establishing in the quickest possible manner very free excretion. This will end the paroxysms by removing the cause, and give the patient the best chance for recovery. It is a common observation that immediately after labor the kidneys of the patient act more freely than formerly, perspiration commonly occurs, vasomotor tension is much relaxed,
the nervous system enters a period of quiet, and the conditions seem favorable for free secretion and excretion. Reasoning from this, physicians have supposed that the first duty in eclampsia was to immediately empty the uterus, and thus bring the patient into that condition most favorable for the resumption of secretory functions. It has been shown that the uterus and its contents do not entirely control eclampsia. A patient has had eclamptic fits after the entire uterus and contents had been removed. Postpartum eclampsia is not a very rare occurrence. A patient may show no sign of this disorder until twelve hours after the birth of her child, as in a case recently observed, in which the first indication of danger occurred at midnight, when a patient delivered on the morning previous suddenly fell out of her bed in a violent eclamptic convulsion.

While it cannot be denied that emptying the womb is a favorable thing for the patient, still it is not sufficient. It is, however, necessary to remove all reflex irritation of the central nervous system originating in the uterus. Thus, if the membranes are tense, they should be ruptured, and intrauterine tension thus relaxed. If the womb is acting and the patient is endeavoring to expel the child, labor should be hastened by every possible means. If the os and cervix are not dilated, but the womb is active and dilatation is abnormally slow, it should be furthered by manual dilatation, by the use of elastic bags, or by incising the cervix. If, however, the patient is in a comparatively early period of gestation, the womb entirely quiescent, the child's movements not excessively violent, the rapid emptying of the uterus will do the patient no immediate good, but will add the shock of operation to the burden under which she is laboring.

The ideal method of emptying the womb in eclampsia would be the Cesarian operation. This has been performed in a number of cases, and on one occasion I delivered a dead child by this method and was surprised to observe the great improvement in the mother's condition. She perished some days later, and autopsy showed highly advanced disease of the kidneys and liver.

An interesting case of Caesarian section for eclampsia is recently reported by Hillman,* who saved the mother, the child perishing. He collected forty cases in which this operation was performed. Twenty-one of the mothers perished; nineteen recovered. One of the cases was that of twins, and of the forty-one children, eighteen perished and twenty-three survived. In seven of these patients eclampsia recurred after the operation. This operation is admissible in eclampsia only when the cervix is tightly closed, when efforts at elimination promptly pushed and closely watched meet with no response, and when edema of the lungs has not supervened. The performance of post-mortem Cesarian section in eclampsia may be rendered unsuccessful, in my experience, by the death of the fetus from the poisons which destroyed the life of the mother. In this instance the child, though robust, perished two weeks after birth from interstitial nephritis and lesions of the liver.

To secure prompt elimination in eclamptic patients, as many organs as possible must be roused to activity by the most direct and efficient agents. The patient should be placed in a complete hot moist pack. If she is conscious, she should swallow five grains of calomel and ten grains of bicarbonate of sodium. The large intestine should be thoroughly douchcd with warm soap-suds, followed by a copious irrigation with from one to three gallons of normal salt solution. A soft rectal tube should be introduced as high as possible, and the flushing should be as thorough as possible. By separating the patient's limbs, wrapping each in separate blankets, the pack may be continued while the intestinal irrigation is going on. The application of cold to the head and the prompt use of chloroform should a convulsion begin will control restlessness and the eclamptic fits. If the patient be unconscious, the stomach should be washed out thoroughly and the calomel and soda introduced through the stomach-tube.

The question of bleeding in eclampsia has occasioned wide discussion. Theoretically, to remove a large amount of poisoned blood, to lessen the tension of the pulse, and to secure the quiet which follows bleeding in many other conditions, would seem an ideal result. Practically, however, the amount of blood which can be drawn does not remove a large quantity of poisonous material, while the ordeal of labor which is still before the patient in many cases is better met with the full amount of blood than with a lessened supply. Attention has recently been drawn

---

*Monatsschrift f. Geburtshilfe und Gynäkologie, Band 10, Heft 2, 1899.
to the advisability of bleeding, followed by intravenous transfusion of normal salt solution. This has not yet given brilliant results, but in view of the prompt stimulating effect of intravenous transfusion it is justifiable and should meet with a more extended trial. Those who do not believe in so radical a procedure agree with me that the prompt introduction of large quantities of normal saline solution by hypodermoclysis is followed by the best results.

At the present day the balance of opinion is distinctly against the use of pilocarpine, of large doses of morphine, and of large doses of chloral and potassium bromide, in the treatment of eclampsia. There is, however, a considerable mass of evidence to show that, in the absence of bleeding, veratrum viride by hypodermic use lessens the pulse-rate and arterial tension, promotes relaxation of the neck of the womb, and assists in controlling the patient. I should say then that, in cases where bleeding was not practiced, hypodermoclysis and the use of veratrum viride would accomplish less promptly the same result. Whether the one method is much better than the other at the present time remains to be proven.

The use of the methods described should be continued as constantly as possible until the intestines have been emptied, the secretion of urine has begun, the patient has sweated freely, and labor has shown a tendency to begin or to remain entirely quiescent. Injections of salines and glycerin into the bowels, or of oil and soap-suds, may be thoroughly used to bring about the emptying of the intestines. It may be necessary to employ croton oil, placing two or three drops in a teaspoonful of sweet oil far back upon the patient’s tongue. The pack should be repeated as often as necessary, and a thorough and vigorous effort made to secure elimination. After the intestine has been emptied, it must be remembered that the patient will be in need of stimulation. Rectal injections of peptonized milk and whiskey, or of freshly made hot coffee well diluted, may be employed. Digitalis may be used by hypodermic injection, and the action of the heart sustained in that manner. In favorable cases labor will have declared itself and the physician should proceed by dilating the womb and promptly removing the fetus and its appendages. This is usually followed by the cessation of convulsions and the gradual establishment of consciousness and free secretion. In desperate cases, when elimination cannot be started, when labor does not begin, there is but one recourse left, and that is to empty the womb in the quickest possible manner and to continue the effort to start elimination while stimulating the patient. Here the choice of a method of delivery will be decided by the experience of the operator, and the facilities under his control. In a well appointed hospital, under aseptic precautions, the womb could be most quickly emptied by the Cesarian operation. In a private house with but limited facilities a rapid manual dilatation of the womb or the incision of the cervix as practiced by Dührsen, followed by version or the use of forceps, will suffice. As soon as labor is over the physician must return to his efforts to secure elimination and to sustain the patient’s strength by appropriate stimuli. In the period after labor in which the patient has begun to eliminate slightly, but is still restless and semi-delirious, morphine or codeine fills a useful place. Should heart action be feeble, and the tone of the vessels deficient, morphine may be used with atropine, and in alternate doses strychnine may be injected. Rectal stimulation and the free use of water as soon as the patient can swallow will usually tide her over the reaction from labor.

The child born of an eclamptic mother must be carefully watched. If premature, it should be placed in an incubator, the intestine thoroughly drenched with warm slightly alkaline water once daily. Care should be taken to avoid chilling the child in any way, and it should be given as much water as it will take. It should not nurse from the mother for ten days after her recovery from eclampsia. If healthy breast milk is available, this may be diluted one-half with warm sterile water and dropped into the mouth by a medicine dropper. If such is not available, pancreaticized diluted cow’s milk may be employed.

The very interesting question of prognosis naturally arises: What determines the successful or unsuccessful issue of a case of eclampsia? In reply, it is my belief that the fate of many an eclamptic woman is decided before the first fit. The extent and duration of the degeneration of the kidney and liver epithelia determine the possibility of the patient to secrete and to free herself from poison. If the toxemia has not been long continued and the patient is naturally a person of sound tissues, her recovery will depend upon the promptness and vigor of her treatment, and most of all upon its early application. If, on the other hand, the tox-
emia has been long continued, the patient is a woman who has borne many children and is debilitated from other causes, or if she is a primipara above the average age, her chance for recovery is exceedingly bad. The attention of physicians should be directed first of all to the paramount importance of diagnosticating and treating toxemia, and secondly, to the fact that if eclampsia occurs, and the physician cannot at once apply in a vigorous manner the best methods of treatment, he should instantly summon the proper assistance or send his patient where she can obtain it. In the presence of eclampsia no one is justified in giving a few experimental doses, or in waiting to observe the action of any particular remedy. As much as possible must be done for the patient, and that at once.

THE TREATMENT OF ECLAMPSIA.

By James Clifton Edgar, M.D.,
Professor of Obstetrics and Clinical Midwifery in Cornell University Medical College; Physician to the Mothers’ and Babies’ Hospital and to the Maternity Hospital.

1. Preventive Treatment of Puerperal Eclampsia.—Our present knowledge of the causation of puerperal eclampsia, meager though it be, furnishes us with the key to the preventive treatment of the condition, still with a working hypothesis, namely, the early condition of the preeclamptic state. To accomplish this, something more than a perfunctory monthly or bimonthly examination of the urine for the presence of albumin is called for, since non-albuminuric eclampsia occurs in from nine to sixteen per cent of cases, and it would appear to be quite as fatal as, if not more so than, an eclampsia accompanied by albuminuria. Something more is demanded than the late recognition of renal insufficiency, as it shows itself in a marked diminution in the quantity of urine, specific gravity of the same, and amount of urea excreted.

When we shall accustom ourselves to watch our cases of pregnancy, not only for the physical signs of pronounced renal inadequacy as an index of an approaching eclamptic attack, but also for the general symptoms of the overcharging of the blood with toxic material—as high arterial tension, headache, gastric disturbances, physical and mental lassitude—and further for failure of the bowels, liver, skin, and lungs properly to perform their functions, and intelligently treat the same, then, and only then, shall we have done our whole duty by our patient, and done all in our power to correct the preeclamptic condition and avert an impending eclampsia.

We should formulate our line of treatment of this preeclamptic state somewhat in the following manner:

1. Reduce the amount of nitrogenous food to a minimum.
2. Limit the production and absorption of toxic materials in the intestines and tissues of the body, and assist in their elimination by improving the action of (a) the bowels, (b) the kidneys, (c) the liver, (d) the skin, and (e) the lungs.
3. If necessary, remove the source of fetal metabolism and of peripheral irritation in the uterus by the emptying of that organ.

Our first indication—the reduction of the amount of nitrogenous food to a minimum—can best be fulfilled in an exclusive milk diet, to which, as the symptoms subside or disappear, can be added fish and white meats. I have found it not only safer, but less trying to the patient, to commence with an absolute milk diet, than to compromise and afterward be compelled to cut off all but the milk. For our second indication—that of elimination—we must first secure an abundant supply of pure air and water. This may be assisted by moderate exercise or light calisthenics or massage, in certain instances. For the bowels I advocate daily doses of colocynth and aloes at bedtime, followed by a saline in the morning. For the liver an occasional dose of calomel and soda at bedtime, followed in the morning by one of the stronger sulphur waters, as Rubinat, Villacabras, or Birmensdorf. Increased diuresis is secured by maximum doses of glonoin. The action of the skin is encouraged by encasing the body in wool or flannel underclothing, by massage, by the warm bath, hot bath, hot pack, or hot-air bath, according to the urgency of the case.

I am accustomed in instances of eliminative insufficiency to give at bedtime twice weekly, or more frequently if necessary, a tablet composed of calomel, digitalis, and squill, each one grain, and muriate of pilocarpine one-twentieth of a grain. This is followed in the morning by a full dose of Villacabras water. I have found a decided diaphoretic-diuretic action to follow the administration of such a combination, with the additional prompt action upon the liver and intestines as well. So of our five eliminative processes four are stimulated to more energetic action by its use.

Although jaborandi has been practically
abandoned as a diaphoretic in the presence of an eclamptic attack, I know of no good reason contraindicating its use in this, the preeclamptic, state in the absence of pronounced cardiac disease, and I advocate its use for its diaphoretic and diuretic actions.

Finally, when exercise cannot be taken and an abundant supply of fresh air is wanting, oxygen inhalations will prove of service. Some preparation of iron will also be called for, such as the tincture of the chloride, or Basham's mixture.

This, then, is the general hygienic and medicinal treatment of the preeclamptic state. No hard and fast rule can be laid down. Every case must be treated on its merits. In one a restricted diet and mild stimulation of the renal and intestinal functions is sufficient, and the patient may be allowed to be about and even exercise in the open air, her skin being protected from sudden changes by being encased in wool or flannel. Other more pronounced cases of eliminative insufficiency must be kept absolutely quiet in bed, upon an exclusive milk diet, and the stimulation of all the eliminative organs must be resorted to, to remove the symptoms of impending eclampsia.

But it must be kept ever before us that the hygienic and medical treatment is only of secondary importance to the milk diet, and that the latter is the foundation of the preventive treatment of puerperal eclampsia. Given a case in which in spite of exclusive milk diet, and the vigorous stimulation of the five excretory outlets already mentioned, the symptoms and signs of the preeclamptic condition continue or at any time become urgent, the indication is to induce artificial abortion or premature labor.

I cannot understand the position of those authorities (notably of the British school of midwifery) who advise against inducing labor in the presence of urgent symptoms of the preeclamptic state.

The arguments that by the methods usually in vogue induced labor increases reflex excitability and precipitates convulsions; that by the same methods, because of the time necessary to remove the barrier of the cervix, the patient's fate is sealed before the delivery is effected; and, moreover, that the onset of labor increases the danger to the patient, are good ones and must demand our attention.

In answer, I would state that our methods of terminating the pregnancy need not increase reflex excitability, and if perchance they do, the excitability is readily controlled for the time necessary to accomplish our ends; that the time necessary is, in most cases, very short; and finally, that to-day the onset of labor and the termination of pregnancy may be practically brought about at one and the same time, and we have no prolonged or tedious labor to react unfavorably upon the patient.

I believe in a rapid manual dilatation of the os in these cases, but only after the cervical canal is in a condition favorable for its safe performance. Moreover, I would insist upon a complete dilatation of the os before delivery is undertaken.

II. The Curative Treatment.—In the presence of an eclamptic attack we face a desperate condition. The latest statistics from various parts of the world still place the maternal mortality at from twenty-five to thirty-five per cent. As long as the pathology of eclampsia remains obscure there can be no rational curative treatment of the condition. My experience does not permit of my recommending any single treatment. Many subjects recover, no matter what the treatment, many die in spite of treatment, and others do well without any treatment at all. No single treatment can be recommended; each case must be managed according to the indications present. My experience has taught me that not a single but a combined treatment promises best for saving the lives of mother and child in the event of an eclamptic seizure. I would offer for this combined treatment three indications, as follows:

1. Control the convulsions.
2. Empty the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the patient as possible.
3. Eliminate the poison or poisons which we presume cause the convulsions.

Although I have named these indications in the order of their importance, still I often carry them all out at one and the same time. In another class of cases I fulfil the first and third, and wait for a suitable moment to carry out the second. The third indication —elimination—should really go hand in hand with the first two, and be put into action at one and the same time with them.

1. Control the convulsions. There is to-day a wide range of opinion regarding the relative value of the various medicinal means employed to control eclamptic convulsions. That eclamptic attacks must be controlled,
that the danger to mother and child is in
direct proportion to the number of convulsions occurring before the emptying of the uterus, most observers are agreed. The four medicinal means most certain and safe as antieclamptics are chloroform, morphine (hy-
podermically), veratum viride, and chloral hydrate, the latter alone or combined with sodium bromide. It would appear from the Transactions of the last International Con-
gress of Obstetrics and Gynecology that of these drugs morphine is most frequently re-
lied upon. My preference is for chloroform, veratum viride, and chloral, in the order named. Until three years ago I used mor-
phine freely in eclampsia, but since have abandoned its use almost entirely, as I be-
lieve it prolongs the posteeclamptic stupor and increases the tendency to death during coma by interfering with the eliminative
processes.

Second only to chloroform in value is veratum viride. Provided the pulse be
strong as well as rapid, it is the most certain means at our command for temporarily and
even permanently controlling the convulsions. When the pulse is weak I rely upon mor-
phine hypodermically, chloroform by inha-
lation, and chloral by rectum, with stimulation
if necessary. As a temporary measure in antepartum and intrapartum and even as a
curative means in postpartum eclampsia, veratum viride will, I believe, accomplish
all that has been claimed for it.

Veratum viride reduces the pulse-rate, and convulsions are practically unknown with
a pulse-rate of 60 or under; it reduces the temperature; it relaxes and renders more
yielding the rigidity of the cervical rings; it
causes prompt diaphoresis and diuresis, so
that it aids not only in the fulfilment of our
first indication, the control of the convulsions,
but in the third, the elimination of an un-
known poison, as well. My practice has
been to rely upon chloroform, veratum viride, and morphine or chloral as temporary
measures, and the prompt emptying of the uterus permanently to control the convulsions.

2. Empty the uterus under deep anesthesia by some method that is rapid and that will cause as
little injury to the woman as possible. Those
who follow the teachings of Charpentier of France, and Winckel of Germany, namely,
that the uterus in eclampsia should be left
alone, except after full dilatation of the os,
as the irritation of inducing labor or arti-
cficially dilating a cervix precipitates con-
vulsive attacks, will, I believe, see many cases
lost that could by prompt and intelligent
measures be saved. It would appear from
careful observation that the danger is prac-
tically over in some ninety per cent of cases
the moment the uterus is emptied, if accom-
plished early in the attack. Not that by this
means the convulsions always cease, but they
become less dangerous, and the case becomes
one of postpartum eclampsia, in which the
mortality, as I have stated, is only seven per
cent.

Although one can scarcely find an authority
to-day, as shown by the reports of the last in-
ternational congress, who absolutely rejects
local interference in the presence of ante-
partum or intrapartum eclampsia, still au-
thorities differ widely as to the extent to
which such interference shall be carried out.
Charpentier, in 1892, as the result of an exhaus-
tive analysis of four hundred and fifty-four cases of eclampsia, and again in
1896 as the result of further observation,
practically arrives at the same conclusions,
namely: (1) That labor should be waited
for and terminated naturally whenever pos-
sible. (2) That induced labor should be re-
served for exceptional cases in which medical
treatment has entirely failed. (3) That in-
terference should be delayed until the cervix
is dilated or dilatable, so as to avoid danger
to the mother; that in eclampsia Caesarian
section, manual dilatation of the cervix, and
especially deep incisions of the cervix, are
absolutely unjustifiable.

During pregnancy and the early part of
labor four procedures are offered for rapidly
emptying the uterus, viz.: (1) Caesarian sec-
tion; (2) mechanical dilatation of the cervix
(various methods); (3) deep incisions which
at once completely remove the barrier of the
cervix; (4) combined mechanical dilatation
and deep cervical incision.

The first method, Caesarian section, for
the relief of eclampsia, still carries with it a
high mortality (36.26 per cent, according to
Charpentier's figures); moreover, there are
many objections to its employment, as the uterine atony and hemorrhage, the irritation
of the uterine and abdominal scars and of
the curative peritonitis about the uterine su-
tures, all of which are to be avoided as
exciting causes of subsequent eclamptic
seizures. The second method, the mechani-
cal dilatation of the cervix and the imme-
diate extraction of the fetus, appears to be
the popular method of the day. Properly
performed it is safe and efficient. Before
dilatation is well advanced, however, from forty minutes to an hour and a half is necessary safely to carry it out, and certain conditions of the cervix, even in this time, refuse to yield to manual dilatation or result in lacerations into the lower uterine segment. The third method of delivery, by deep cervical incision, offers us a surgical means for emptying the uterus in from five to ten minutes, provided the supravaginal portion of the cervix has disappeared or is made to disappear by appropriate means. The fourth or combined method is a combination of the second and third methods, and is applicable to cases in which the supravaginal portion of the cervix is still present and rapid emptying of the uterus is demanded. Here mechanical dilatation of the os until the internal os has been caused to disappear is made use of, and the dilatation then in an instant completed by the incisions. The third method and its modification, the fourth, are comparatively new, and we have few statistics as to the results of the operation. I believe a rapid manual dilatation of the os and subsequent extraction of the fetus will fulfill the indications in most cases, but unless this can be intelligently carried out, with a due appreciation of the mechanism of dilatation, especially in primipare, a purely expectant treatment will give better results. Unfortunately puerperal eclampsia is four times more frequent in primipare than in multipare, although, on the other hand, the mortality is greater in the latter.

I believe a warning should be sounded against the careless undertaking of rapid manual dilatations of the os, particularly in eclampsia. Uterine rupture and death have, we know, been the outcome. Moreover, undue shock has resulted from the dragging of a fetus through an imperfectly dilated os, to say nothing of the loss of the child.

In placenta previa the hemorrhage and the resulting anemia of the lower uterine segment and cervix render these parts more readily dilatable. In eclampsia the reverse obtains, as I have already hinted. Hence it is that in eclampsia, in instances in which the internal ring of the os has been drawn up into the body of the uterus and the external ring remains rigid and tense, particularly in primipare, and there is urgent need of rapidly terminating the labor, I prefer four clean incisions extending from the edge of the os to the uterovaginal junction, in order to save the patient from the greater dangers of rapid manual dilatation.

In the second place, I believe a warning is not out of place against the premature extraction of the fetus before full dilatation has been secured and the external ring of the os paralyzed. Premature extraction, under such circumstances, has been known to result in many unnecessary and dangerous lacerations of the lower uterine segment, and an increase of the mortality for the child and mother.

3. Elimination of the poison or poisons which we presume cause the convulsions. For the elimination of the toxic materials from the blood and tissues I have nothing new to offer. I believe it essential, however, to rely not upon one but upon all the eliminative organs of the body, and, moreover, that the fulfillment of this third indication in the treatment of eclampsia should go hand in hand with the first two already mentioned. To this end I secure catharsis as early and as promptly as possible by the administration of croton oil, compound jalap powder, or calomel, followed by salines and high enemas of sulphate of magnesium. In the coma or post eclamptic stupor of the condition I have relied mainly upon the repeated administration of concentrated solutions of sulphate of magnesium or Villacabras water, by means of a long rectal tube high up in the descending colon. The hypodermic administration of magnesium sulphate I have found too slow and uncertain to be of any use. Diuresis I obtain by dry or wet cups over the kidneys, followed by hot fomentations. The value of glonoin as a diuretic and antieclamptic, the latter by reducing the arterial tension, I believe cannot be overestimated. Second only in value to glonoin I consider veratrum viride. I give it at this time for the same reasons and looking for the same results as when I administer it in the preeclamptic condition. Diaphoresis is encouraged by means of the hot-air bath or the hot pack, my preference being for the former. Pilocarpine as a diaphoretic in the presence of an eclamptic attack I utterly reject, because of the danger of edema of the lungs and glottis, which it may produce. I have seen these conditions follow promptly upon its administration.

The drawing off of large quantities of toxic liquids in the form of blood or serum, by means of venesection, catharsis, diaphoresis, diuresis, followed by the replacement of the same by intravenous, stomachic, rectal, or hypodermic means, causing a washing or disintoxication of the blood and tissues, as it were, has thus far proved of doubtful value. In instances of collapse, however, with the
small compressible pulse, the introduction into the blood of a normal saline solution is of the same value here as in collapse under other circumstances. As a general stimulant, to assist in the elimination from the lungs and to prolong life in the post eclamptic stupor or coma, I have found the free administration of oxygen of the greatest value. Further, alcohol will often be needed as a stimulant during and after an eclamptic attack, and strychnine in the postpartum state and in the face of threatened collapse—although for physiological reasons it would seem to be contraindicated—has served me well.

Finally, although no one has been or is a firmer believer than the writer in the efficacy of a prompt removal of fetal metabolism and of irritation for not only the control but the cure of the eclamptic condition, still I beg to enter a protest, first, against the careless use of the term "accouchement forcé" as-applied to the rapid, scientific, and intelligent emptying of the uterus; and secondly, to the easy confidence with which this accouchement forcé has been recommended as the best if not the only means at our command for the control of eclamptic seizures, without attaching sufficient importance to the condition of the cervical barrier. By accouchement forcé we understand to-day three operations, namely, (1) the complete instrumental or manual dilatation of the cervical canal, followed by (2) either combined or direct version, or the application of the forceps, and (3) the immediate extraction of the child.

TREATMENT OF PUERPERAL ECLAMPSIA.

By A. F. A. King, M.D.,
Professor of Obstetrics and Diseases of Women in the Medical Department of the Columbian University,
Washington, D. C.

Assuming the convulsions to be of uremic origin, my treatment is hydragogue cathartics, the hot bath, either water or vapor, or the hot wet pack to promote diaphoresis; then in succession over the kidneys, cupping (dry or wet, as the patient may be respectively anemic or the reverse), mustard plasters, once only, and continued only long enough to redder the skin; then hot poultices of flaxseed meal and digitalis leaves. When renal congestion has thus been relieved (not before) I give digitalis and citrate of lithium internally to increase renal excretion. Place the patient in Sim's position, or in any other that will divert the pressure of the gravid womb toward the diaphragm and away from the pelvis.

To control the convulsions themselves when they have actually occurred, I give large doses of fluid extract veratum viride with morphine, hypodermerically; and in anticipation of each convulsion, just as it is about to begin, a cautious inhalation of chloroform.

Of course, it is desirable to deliver as soon as practicable, usually by forceps, but if the convulsions can be kept in abeyance and labor proceed by itself without interference, so much the better. All violent manipulations with instruments or otherwise should be avoided, if it can judiciously be done.

I think there is often a want of sufficiently strict observance of the patient's environment; I mean the room should be kept absolutely quiet—no slamming of doors, clattering of crockery, or talking aloud. Let the room also be dark.

One thing more: it is usually advised to place something between the teeth to prevent the tongue from being bitten. It does not occur to most of us that this clenching of the tongue by the teeth is sometimes a natural conservative process to save the patient's life by preventing the tongue sagging backward and thus shutting down the epiglottis over the glottis and stopping respiration, when the convulsion is over. In such case the lower jaw should be depressed and the tongue drawn forward with forceps. I am convinced that cases sometimes die after one convulsion from this falling back of the tongue.

THE TREATMENT OF PUERPERAL ECLAMPSIA.

By Edward Reynolds, M.D.,
Instructor in Obstetrics and Assistant in Gynecology in Harvard University.

The following is a statement of my practice in puerperal eclampsia, by which I mean to include the several varieties of obstetrical eclampsia. I believe we know so little of the pathology of the eclampsia of gestation that our knowledge of it can be summarized by saying that the convulsions are the result of the altered physiological state of the pregnant woman (which state of course persists in a lessening degree through the early part of the puerperium), and is attended by a decreased activity of the kidneys and an increased irritability of the convolution centers.
I believe that with this limited knowledge of the pathology of the affection the treatment of it is necessarily empirical and can rationally be directed merely to the removal of the only two facts which we are sure about — i.e., the activity of the kidneys is lessened and the irritability of the convulsion centers increased. These two factors, however, vary in their importance in individual cases, and our empirical treatment must therefore vary with them. We are enabled in some cases to make our treatment a little better than symptomatic, and a little more directed to a radical cure, by the fact that we know the condition to be dependent upon pregnancy, and may therefore in the eclampsia of pregnancy and parturition aim to remove the cause of the eclampsia by a prompt termination of the pregnancy. For prophylaxis I am a strong believer in the efficacy of diuresis, catharsis, and diaphoreosis, obtained by the forced ingestion of fluids, hot immersion baths, and saline cathartics, but they should be reinforced by rest in bed and a milk diet (this complete or partial, according to the severity of the case), and the exhibition of mild sedatives, such as the bromides.

When even one convulsion has actually occurred I believe it is important that one should remember that if he loses a mother from eclampsia he will almost always lose the child also; and as it has been my experience that prompt delivery immediately after the advent of convulsions usually saves the mother, while a temporizing policy frequently loses both, I have come to the conclusion that the probable loss of maternal and fetal life due to temporizing methods far outweighs the certain loss of some immature feta by prompt delivery, and now advocate immediate delivery under ether at one sitting for all cases of eclampsia in which one undoubtedly convulsion has occurred before the delivery of the child.

After delivery or in the puerperium I use catharsis, obtained by calomel and croton oil if the patient cannot swallow well enough to take salines, diaphoresis secured by the hot-air bath, and diuresis obtained by the administration of the largest amounts of water which the patient can be induced to swallow, fortified by citrate of potash or cream of tartar where the total quantity taken is small. I graduate the dose of my cathartics, and the heat and duration of my hot-air bath, by the condition of the patient’s pulse, aiming to produce free sweating and three or four loose motions in the twenty-four hours if the patient’s strength permits. I occasionally use a single hypodermic injection of one-sixth grain of pilocarpine in cases where I am unable to obtain diaphoresis without it; but I am afraid of this drug, as I have frequently seen it produce a watery secretion from the lungs rather than from the skin. I am not much afraid of its effect as a cardiac depressant unless in very weak women. I also use sedatives almost as a routine, giving bromides, or large doses of the bromides in combination with small amounts of chloral, to cases in which the urinary suppression is well marked and appears to be the main feature, but using chloral to the point of physiological effect, with or without bromides, in cases in which the convulsions have come with comparatively little disturbance of renal function. I prefer chloral to morphine, both for the theoretical reason that morphine decreases the secretions, and also on the empirical ground that my experience has led me to believe that it works better in practice. I have used venessection and the effusion of salt solution under the breasts, but have observed little or no favorable effect from either. It is fair to say that my employment of these methods has been limited to unfavorable cases. I have not personally employed veratum viride, but have seen in consultation a good many cases in which it had been previously employed without the good results so often claimed for it.

I shall look forward with interest to reading the other contributions to this symposium, as the subject is so very obscure that it seems well suited for investigation by the collective method, but I hardly believe that we shall obtain any marked improvement in results until we have learned something more about the pathological cause of the affection.

THE TREATMENT OF ECLAMPSIA.

By Richard C. Norris, M.D.,
Physician in charge of the Preston Retreat, Philadelphia.

The most efficient treatment of eclampsia is its prevention. Until physicians realize that all pregnant women should be carefully observed throughout at least the latter half of pregnancy, in order to recognize the first appearance of toxemia, this dreaded disease with its high mortality will continue to claim its victims. While the most recent investigations have not demonstrated the actual cause or causes of eclampsia, they all indicate that toxins of unknown composition and of various origins are the underlying factors,
and that these poisons produce their ill effects through the inefficient work of the liver, the kidneys, the bowel, and the skin. An aggravation of the common subjective phenomena of pregnancy will first call attention to a beginning toxemia. Neuralgia of rather obstinate character, irritable temper, excessive vomiting, marked salivation, a heavily coated tongue, hebetude, and other signs of inactivity of the liver, are indications that the organs of defense and elimination are beginning to feel the strain put upon them. The urinalysis at this early stage commonly shows the urine to be free from albumin, but the percentage of urea is decreased, and that of uric acid is increased. The presence of sugar is a certain sign of hepatic deficiency, and indican and peptones may also appear in the urine.

The routine examination of the urine of pregnant women for albumin alone is therefore not enough to determine the appearance of dangerous symptoms. For practical purposes the percentage of urea, the specific gravity, and the amount voided must be determined, and even these only serve as a clinical index of the amount of waste products successfully excreted. A further study of the constitutional signs of toxemia must be made to properly estimate the danger and to learn whether the brunt of the toxins is borne by the central or peripheral nervous system, the circulation, the gastrointestinal, the hepatic, or urinary functions. The weakest function in each individual case will first give way, and first manifest the signs of the ill effect of the toxins. While the indications for special treatment will be made plain by a critical study of individual cases, the most important indications in all cases are to prevent, as much as possible, by diet, the formation of toxins; to aid the liver to destroy them, and the excretory organs to eliminate them. When the urinary analysis and the constitutional signs of toxemia point to a slight deviation from the normal, I have found it sufficient to modify the diet, eliminating nitrogenous foods, and directing an abundance of milk and water, and a mild laxative.

The advantage of calomel as a laxative for pregnant women is very great, since it is probably the best intestinal antiseptic, besides acting upon the liver, the organ that especially requires attention during pregnancy. For graver cases showing marked toxemia, with the percentage of urea diminished below one per cent, the specific gravity below 1010, and the quantity of urine reduced to 800 or 1000 grammes, the most active treatment is demanded. This should include rest in bed, the patient occupying the genupectoral position at intervals compatible with her comfort. An exclusive milk diet until marked improvement occurs is essential. The free use of normal salt solution I have found of greatest advantage. The patient should be placed in the Trendelenburg posture and the colon daily flushed with at least two gallons of salt solution. In very urgent cases hypodermoclysis may be desirable. A hot-air bath or a hot pack should be reserved for cases so alarming as to threaten the necessity for terminating pregnancy.

Of all drugs available for the rapid elimination of waste material I have learned to place most confidence in Epsom or Rochelle salts.

It will be noticed that I have made no mention of the use of drugs which, for their diuretic effect, are frequently employed with great confidence. Digitalis, diuretin, benzoic acid, and similar drugs I have used in the past, but it is my conviction that the more rational plan is to rely upon the mechanical diuretics, such as an abundance of pure drinking-water and rectal injections of salt solution, and upon elimination by the skin and bowels, and thus to save as much as possible the kidneys, whose functional activity has been overtaxed by nature’s efforts at elimination.

There exists considerable difference of opinion as to the necessity for terminating pregnancy in cases of threatening toxemia, and it requires good judgment and a large experience with these cases to decide in individual instances the safe course of action. Analysis of the urine cannot always guide us, nor will a careful study of the constitutional signs of toxemia always determine the question. My experience with cases of toxemia in pregnant women has taught me that the urinalysis may exhibit the gravest changes without marked constitutional evidences of toxemia, while on the contrary, the urine may be only slightly abnormal in a patient showing dangerous symptoms of toxemia. A sudden diminution in the waste products with the appearance of alarming constitutional symptoms is often more favorable because more amenable to treatment than a slowly appearing and gradually increasing toxemia. When the specific gravity of the urine is low, the quantity voided steadily diminishing, the percentage of urea persistently decreasing with or without the presence of albumin, the case is really alarm-
ing and indicates a chronic process which may lead to the gravest dangers.

If any single fact, more than another, can be our guide to determine the necessity for terminating pregnancy, it is that the toxemia has developed steadily and slowly, and that the constitutional signs and urinalysis keep pace with each other in giving evidence of the accumulation of toxins. After observing the progress of a case over a period of a week or two, if the patient’s condition steadily improves the prophylactic measures employed may be continued. If, however, the patient’s condition steadily grows worse, or after showing improvement manifests at intervals sudden relapses, the only safe course is to terminate the pregnancy.

My consultation practice too often has made me realize that the family doctor fails to appreciate the necessity for interference in these grave cases. He will pride himself on successfully carrying many patients to term only to have forced upon him, when he least expects it, the disaster of delay.

Having neglected the opportunity to prevent the occurrence of convulsions, or when the cases are first seen in the convulsive stage of the disease, the indications for treatment are, first, to control the convulsions; secondly, to aid and hasten the elimination of toxins; and thirdly, to deliver the patient as speedily as possible, but in accordance with a conservative obstetrical treatment. The patient should be protected from the violence of the convulsion. Injury to the tongue can be avoided by forcing the handle of a brush covered with a towel between the jaws. The administration of chloroform to control the convulsions, in my experience, has been preferable to hypodermic injections of morphine. A drachm of chloral by enema, repeated four or five times in twenty-four hours, if necessary, is always indicated. Whether veratrum viride or venesection shall be employed depends in great measure upon the character and frequency of the convulsions, the strength of the patient, and the condition of the circulation. In primigravidae, where the pulse is strong and full, the face cyanotic, and the patient herself full-blooded, venesection until a positive effect has been produced upon the pulse has been my practice. In cases less sthenic, where the pulse is weak and running, veratrum viride employed hypodermically in doses of eight minims of fluid extract, repeated at intervals sufficiently often to produce a decided slowing of the pulse, is exceedingly useful.

In a few cases the pulse may be so weak, or even absent, and the heart action so feeble, that strychnine and nitroglycerin are necessary. It will require the best of therapeutic judgment to differentiate between cases requiring the most vigorous means to depress the circulation and those in which stimulation, on the contrary, is strongly indicated. The next indication, to aid elimination, is best accomplished by the injection of normal salt solution under the mammary glands and into the rectum. In combination with venesection, or the use of veratrum viride, the action of the saline solution upon the circulation in restoring tone to the pulse is really remarkable. A hot wet pack, secured by wrapping the patient in blankets wrung out of hot water, will aid the action of the skin. The ill effect of heat upon the intracranial circulation will best be counteracted by an ice-cap on the head.

The tendency in eclampsia to edema of the lungs contraindicates the employment of pilocarpine. I have, however, when the skin is exceedingly dry, found one small dose, one-twelfth of a grain, very efficient in starting a gentle action of the skin, which can then be maintained by the external application of heat, as a hot-air bath or hot wet pack. It is of the utmost importance to secure a free action of the bowels. It has been, in my experience, a clinical observation that the patient’s chance for recovery is always increased when free purgation can be secured. Three to five drops of croton oil in a teaspoonful of sweet oil or butter, placed upon the back of the tongue, will very often prove efficient. A rectal injection of turpentine one drachm, Epsom salts and glycercin each two ounces, water six ounces, is always to be employed.

In my experience no drug is so efficient for rapid elimination of poisonous material as Rochelle and Epsom salts, and if the patient is not comatose between the convulsive attacks, and can swallow, one or the other of these drugs should be given in frequently repeated doses until very free catharsis is secured. In cases comatose and unable to swallow, I have succeeded in obtaining this effect by introducing a large dose, two to four ounces, into the stomach through a stomach-tube.

All authors agree that labor should be terminated as soon as possible. To those who believe that the rapid dilatation of the cervix, incising it if necessary, and the immediate extraction of the child, are necessary
to the proper conduct of the obstetrical treatment of eclampsia, it is my conviction that their arguments should induce them to perform Cesarian section as the most rapid means of emptying the uterus. The mortality of the latter operation under such circumstances is so exceedingly high that it cannot be considered advisable. It has been my custom to rely upon a very aggressive medical treatment to combat the spasms and to eliminate the poison, and then, after sufficient dilatation of the os has occurred, to rapidly deliver with forceps and terminate the labor. If the child has perished, craniotomy of course is the operation of choice.

While it is true that the patient’s chances for recovery are increased the moment she is delivered, the immediate and remote dangers of violent means to effect delivery are also increased, and in my experience they outweigh any advantage from accouchement forcée. The elimination of the poisons threatening her life means more to the patient than a rapid emptying of her uterus by violent means. In the gravest cases where the accumulated toxins have overwhelmed the patient and areas of necrosis are present in important organs, it matters not how rapid the delivery or how aggressive the medical treatment—the patient is doomed. The opportunity to save her life was lost when the termination of her pregnancy was neglected.

Having delivered the patient and having controlled the convulsions, the subsequent treatment during the puerperal period should consist in further elimination of the poison by hot-air baths secured by means of a shoulder of stove-pipe and an alcohol lamp. The cathartic action of Epsom salts should be kept up. The citrate of caffeine in three-grain doses every four hours, watching for its intoxicating effect, I have found especially useful both for its diuretic action and its support to the heart, which has been weakened by the aggressive treatment employed during the convulsive stage of the disease. An exclusive milk diet is always necessary until the patient’s convalescence is well established.

THE PROGNOSIS AND TREATMENT OF NEPHRITIS.

By H. A. Hare, M.D.,
Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Hospital.

No sooner does the physician recognize the presence of inflammation in the kidney than the question arises in his mind and in the mind of the patient, what is the prospect of recovery, and what is the probable duration of life, provided the renal condition is incurable? Before it is possible for us to discuss these interesting points it is necessary to divide the various forms of nephritis into groups which are based upon the renal changes present in each. At the very first we must separate acute diffuse nephritis from the chronic degenerative forms of renal disorder because its causation, duration, and pathological condition is so different from the chronic type that it is an entirely different entity. This fact has been well emphasized, and therefore I need not describe what the anatomical and etiological differences are. Suffice it to state that the prognosis of acute diffuse nephritis is as a rule quite favorable. Thus we find that a large proportion of these cases recover, but the percentage of recoveries is difficult to determine, since other conditions are often associated with the renal change. Thus in the acute nephritis of childhood dependent upon scarlet fever there is, aside from the toxemia which arises from inactive kidneys, the additional toxemia of the scarlet fever poison itself, and in many cases sepsis from infection from other microorganisms, such as the streptococcus, which aid in hastening a fatal issue.

Further, the degenerative changes in the heart and vessels, the pulmonary and pharyngeal complications, and the fever, all tend to throw additional factors into the scale which tend to cause death in scarlatinal nephritis, aside from the evil influence produced by this condition itself. In the case of children the prognosis of an acute nephritis complicating scarlet fever is favorable in direct proportion to the severity of these general influences, and the longer the child survives these inimical influences the greater probability is there of recovery. This is, of course, true of all prognosis, but it is especially true of this period of life, for children possess such wonderful reparative power that if they can but survive the mixed toxemia for a few days there is great probability of the damaged cells in the kidney being repaired or replaced so that normal renal function will be possible. It is true, as is well emphasized by Strumpel, that every case must be judged with great caution, partly because it may be the starting-point of a subsequent chronic renal disease, and partly because dangerous sequelae may develop in cases which at first seem mild.
There are three factors of prime importance in this class of cases: the degree of toxemia or severity of infection; the degree of anasarca, because it shows vascular, cardiac, and renal trouble and produces serious complications by mechanical pressure; and the presence of marked signs of irritation of the nervous system or obtunding of its activity by poisons.

Given a case of acute nephritis in a child, it is evident from what has been already said that if the acute conditions produced by the inactivity of the kidneys can be survived, recovery will in all probability take place. Some of these cases, however, develop such a profound degree of toxemia that the condition is hopeless, all the epithelial cells of the kidney being destroyed and their functions set aside so completely that death ensues before the kidney recovers sufficiently to eliminate toxic materials from the blood. When this condition is developed, remedial measures are necessarily to a large extent impotent, because the condition is so far advanced. As a matter of fact, in the acute nephritis of both children and adults, the largest part of the treatment, if it is to be successful, must be prophylactic, and if precautionary measures are taken grave renal complications can often be avoided. This is well illustrated by those cases of scarlet fever in children in which the primary manifestations of the disease are very mild, so mild that the careless physician and nurse do not insist upon the patient remaining in bed, but nevertheless, in a short time evidences of advanced kidney infection develop and death speedily ensues.

By the administration of mild alkaline diuretics, copious draughts of pure water, and the use of purgatives, which will rid the body of toxic materials through the bowels and improve the abdominal circulation, much can be done toward preventing severe renal involvement. Further than this, by the use of hydrotherapeutic measures, such as cold sponging and friction, which aid the circulation, stasis of the blood and kidney can be avoided and a large amount of toxemia set aside, just as we set it aside in typhoid fever by such measures; and it is a well known fact that, even when toxemia is advanced and renal secretion is scanty, placing the patient in a warm bath and then dashing cold water over the head, shoulders, and back will by the circulatory reaction which develops restore the patient to consciousness, and increase urinary flow. Such treatment probably also increases the elimination of poisons by the skin.

It is well to emphasize the fact that should cold water be employed, active friction must be practiced with it and reaction must be produced, for if friction is not employed, and if the bath is continued for a long period of time so that the circulation is impaired, more damage is done than if this procedure were omitted. In other words, the use of hydrotherapy in this condition must be governed by the knowledge of the methods by which it should be employed.

When we come to the consideration of the two forms of chronic nephritis, the parenchymatous and interstitial, we find that prophylactic treatment can rarely be instituted since both conditions are so insidious in their onset that the patient is usually well advanced in the disease before he presents himself for treatment. Prophylactic treatment in these cases must therefore be devoted to the prevention of the spread of the disease as far as possible, the relief of symptoms which may be annoying or dangerous, and the institution of a course of dietetics and medication which will also tend to relieve symptoms and to enable the patient to avoid throwing extra strain upon the kidneys. In other words, the mode of life to be followed by the patient is an important point with which the physician must deal.

I have recently seen a case in consultation which emphasizes this fact very strongly. A patient, a man of fifty odd years, apparently in perfect health, insisted upon riding some thirty or forty miles on a bicycle at a high rate of speed. The subsequent course of the disease proved that he had been suffering for a number of months with an insidious nephritis, which immediately became severe in its manifestations, causing his death at the end of three weeks. Doubtless the violent strain put upon his heart and kidneys by this exercise precipitated the fatal issue, and had the patient been warned of the danger of such excessive exercise his life might have been prolonged. On the other hand, renal cases should not be deprived of all exercise, unless it is evident that a feeble heart requires rest.

In regard to the question of diet, it is evident that no cast-iron rules could be laid down, and many cases of chronic contracted kidney, unless they are markedly gouty, can have a liberal diet, provided it is one which is easily digested and not calculated to produce gastric and intestinal disturbances. In
other words, these patients need not have their meat cut from the diet list, but should be allowed to take good wholesome food, provided that it is not taken in excessive quantity.

In chronic parenchymatous nephritis it has been held by many practitioners, as is well known, that it is our duty to eliminate from the diet list eggs and red meats; on the other hand, many physicians of large experience are coming to the belief that this is depriving the patient of a large amount of nourishing food which in reality he can take with impunity, provided it is not taken in excess of the needs of the system.

Probably the most satisfactory rule to be followed in these cases is to be governed by the effect of the administration of eggs and meats upon the patient, and upon his elimination of albumin. If on the administration of eggs and meats his albuminuria is markedly increased and he does not seem to do so well in general, it is evident that these articles should be taken from him. If, on the other hand, his general health and strength improve by their use, and the albuminuria is not increased, it is evident that they should be allowed. In some cases, where the albuminuria is marked, the use of albuminous food seems to take the place of the albumin which has been lost through the kidneys.

Of course, in cases of acute nephritis it is advisable to avoid albuminous food until the acute period of the disease is passed by. When there is marked diminution of urinary flow, as we ordinarily find it in parenchymatous nephritis, one of the most important functions of the physician is to increase this secretion. Drugs have been much abused under these circumstances; too often they are administered without clear ideas of what they are to accomplish. If it is believed that the scanty urine depends upon inactivity of the renal epithelium, the administration of caffeine may be wise, or in other instances the production of free diuresis by the use of bitartrate of potassium and juniper berries in infusion may produce the best results. This old combination, which has to a large extent dropped out of use with some practitioners, is much too valuable to be lost sight of.

If, on the other hand, an examination of the heart indicates that this organ is unduly feeble, and that the albuminuria and scanty renal secretion depend upon renal stasis, then digitalis or strophanthus, alone or combined with juniper berries and bitartrate of potassium, is very useful. It has been thought by some persons that it is advisable in this class of patients to increase urinary flow by the administration of copious draughts of pure water. While this may be good therapeutics in a certain number of cases, it should be governed by the dropsical condition of the patient; if there is deficient renal elimination of fluid, because the kidneys are unable to pass it out of the blood, it is manifest that copious draughts of water will not remove impurities from the body, but will simply tend to increase dropsical tendencies.

So far as I know, there are no drugs which distinctly decrease the elimination of albumin in advanced parenchymatous nephritis, and it seems to me doubtful whether the attempts to check the escape of albumin by such drugs are wise, since if they succeed they probably also decrease the elimination of impurities from the blood. Most of these remedies have been astringents which are supposed to act by contracting the renal blood-vessels. There is, however, one drug which ought to be remembered in cases of parenchymatous nephritis, namely, iron. On the other hand, this drug is too much relied on by many physicians; aside from the fact that when given in mixture a diuretic effect is produced, the large doses of iron which are frequently given in this way probably do more harm than good, as they tend to produce constipation, and only very minute amounts of iron can be used. Probably spirits of milder us, when given alone, would produce almost equally good results; and if minute doses of iron were given in pill form, equally good influences would be produced in combating anemia. For the relief of dropsy, or the relief of general anasarca, there is no doubt that hydragogue purgatives are useful in many cases. Oftentimes the unloading of the bowels by the use of purgatives decreases the congestion of the liver which is sometimes met with in these cases owing to secondary cardiac complications, and improves the patient wonderfully. Equally important as, if not more so than, the employment of purgatives, is the use of copious sweating produced by hot-air baths or by the hot pack. These therapeutical measures are of the greatest possible value and are so well known that it is not necessary for me to describe them in this paper.

In my experience the so-called medicinal diaphoretics are not of any great value. The profession is learning more and more that
pilocarpine is too much of a heart depressant to be employed in most of these cases, and either because of its depressing effect upon the heart, or by reason of its causing a profuse outpouring of the secretions into the bronchial tubes, its use is apt to produce that gravest of all conditions in nephritis—edema of the lungs. I do not think it ought ever to be employed in combating uremia, except perhaps when given in very minute doses to aid the action of the hot pack, and then the circulatory system should be assisted by minute doses of strychnine, which drug however may be contraindicated if the poisons of the disease seem to be producing great nervous irritation.

This important subject can well take much more of the space at my disposal, but the limitations which necessarily exist force me to close. In doing so, however, let me remind you that when uremia is once well marked, hypodermoclysis or intravenous transfusion of normal saline solution will oftentimes produce excellent results. Better results are obtained by this means in cases of uremia coming on as a result of chronic contracted kidney than in those due to parenchymatous nephritis, and when dropsy is marked they are least valuable.

In plethoric patients, or others with a high arterial tension, venesection is often advantageous.

Last of all, I may say a few words in regard to the contradictory views concerning the use of morphine in uremia. These contradictions I believe to be more apparent than real. Uremia is the result of the complex poisoning; in some instances poisons seem to be present which exercise a powerful depressing effect upon the nervous system, in others the effect seems to be that of irritation. Probably those cases which have been greatly benefited by the administration of morphine are cases in which the sedation of the nervous system produced by this drug is beneficial, whereas in those cases in which this condition has not been present the administration of morphine has simply increased the nervous atony. On the other hand, Sir George Johnson has recorded instances in which in his opinion the employment of morphine has caused rapidly recurring and ultimately fatal convulsions, perhaps by diminishing the excretory work of the kidney and producing constipation; and Tirard, in his recent book upon renal disease, uses these pregnant words in regard to the use of morphine: "I have always refrained from the use of a drug which might produce present comfort at the cost of the life of the patient."

As I have already said, it is evident that the question of the administration of morphine must be decided in each individual case, and that it cannot be ordered for or denied to every patient who presents himself with this grave malady.

**Anesthetics, Local and General, as Applied to Taxis, Herniotomy, and Operations for the Radical Cure of Hernia.**

By J. Coplin Stinson, M.D., C.M.,
San Francisco, Cal.

The administering of a general anesthetic and the production of local anesthesia by medicated fluids in operations for hernia are matters of the utmost importance and require considerable skill, tact, and judgment.

Local anesthesia should be used in hernia operations:

A. When a general anesthetic cannot be administered without danger.

1. In some cases of strangulated hernia, when there is: (a) great distention of the abdomen; (b) a weak and rapid or failing pulse; (c) excessive vomiting which persists after washing out the stomach; (d) when the patients are constitutionally weak; (e) in those cases where the patient's capacity to appreciate pain is blunted, or he is too weak for a general anesthetic.

2. In marked organic diseases of the heart, liver, lungs, and kidneys; atheroma; advanced acute and chronic affections of the respiratory tract, e.g., severe bronchitis; old emphysema and asthma; and advanced tuberculosis.

3. In old age, chronic alcoholism in persons past fifty years of age, and in markedly debilitated persons.

4. In marked arteriosclerosis.

5. In late operations, when patients are liable to have severe postoperative anesthetic shock.

B. When the patient will not submit to a general anesthetic. When local anesthesia is used little or no pain will be experienced till the sac is opened and the contents handled. By working rapidly a radical operation can be performed with but moderate pain. It is impossible to tell beforehand how long an operation will last, so that sometimes the finishing steps of the operation are painful,
but can be completed satisfactorily by using considerable persuasion.

As a rule inject hypodermically fifteen minutes before the operation one-third to one-half a grain of morfine when using local anesthesia. If cocaine is employed as the anesthetic, use a 1:100 solution in distilled water, which is warmed beforehand. Anesthesia lasts from thirty to fifty minutes, about the time required for an operation. The writer has never seen marked symptoms of poisoning when solutions are used in the strength recommended, and the anesthesia produced is as satisfactory as when stronger solutions are employed. Use cocaine as a routine, but if there is a clear history of poisoning from its previous use then employ eucaine. Begin the operation about three minutes after the injections and before the fluid is absorbed. Injections should not be made into the subcutaneous tissues, as they are especially apt to be followed by rapid absorption and toxic symptoms. Introducing the fluid into the Malpighian layer produces rapid, certain, and safe anesthesia.

Technique of Local Anesthesia.—The aseptic injecting needle is carried obliquely through the epidermis till the point is in the Malpighian layer. A minim of the 1:100 solution is injected, which causes whitening of the epidermis, and the needle is then forced along this layer and sufficient drops injected from time to time to produce the whitening until the needle is inserted its full length. The needle is all withdrawn except the point, and through the same puncture the needle is carried in the same line, but in the opposite direction, and sufficient drops injected. A two-inch needle used as just described, and inserted at the center of the field for the incision, can anesthetize through the one puncture about four inches. Deep injections (1:200) may be made into the aponeurosis of the external oblique, but the pain of incising and dissecting this and the deeper layer is not severe. As a rule deep injections should be avoided, for this and other obvious reasons.

Eucaine is less toxic than cocaine, but the anesthesia is slower in onset, and of less intensity, yet thoroughly efficient. It does not decompose on boiling, and can be used in two-per-cent solution. Anesthesia is complete in about four minutes and lasts from twenty minutes to an hour. It is unusually causes sloughing, which constitutes the serious objection to its use in aseptic cases; while in a few instances it has produced constitutional symptoms of considerable danger. Hemorrhage is more abundant when eucaine is used, as it produces hyperemia, and the injections are also a little more painful than cocaine.

General Anesthetics.—The administering of a general anesthetic is also a practical matter. Timidity or bad judgment of the anesthetist is most likely to result in an imperfect or too profound narcosis, and consequent death on the table or postoperatively.

It is most essential that the man at the mask should be reliable, experienced, know how much to give and when, how not to give too much, know when to give stimulants, and when to warn the surgeon to cease his work.

All mixtures such as the A. C. E., ether, benzine, chloroform, etc., should be avoided. Their general use has not inspired confidence in their absolute safety; their great and unequal volatility and other bad qualities seem to overwhelm some patients, producing great paller, frequent pulse, or interference with respiration. Ether and chloroform, according to which is indicated, are the preferable anesthetics. In all operations the patients should be kept warm by sufficient and suitable coverings, hot-water bottles, etc.

Regarding the Choice of Anesthetics.—In general ether is to be preferred to chloroform, as it is safer. Nausea and vomiting are slightly less after chloroform, and this is of some importance in hernia operations. Sometimes vomiting after an operation is due to iodoform absorption, so iodoform gauze, powder, etc., should never be used. Fifteen minutes before chloroform is administered one should always inject strychnine, $\frac{1}{2}$ grain hypodermically. With this stimulant to the respiratory and cardiac centers the patients will, as a rule, if the chloroform is administered properly, take the anesthetic well. Whenever it is possible, for the day preceding an operation for hernia, safe diet should be insisted upon, and the bowels should be moved by a laxative, followed by an enema, which is given several hours before anesthesia, so as to thoroughly empty the lower bowel of lumps of feces. Never give morfine before administering chloroform, as it may put the patient in great danger; it obscures the symptoms and signs during anesthesia and sometimes subsequent to it.

A weak, dilated, and laboring heart are contraindications against chloroform. Chloroform to be most successfully administered should be given a drop at a time on a
thin gauze inhaler. One drop a second is enough in most cases, and after the patient is under one drop every two or three seconds or even less frequently is sufficient to maintain anesthesia for a hernia operation.

The anesthesia must not be hurried, and the patient is told to breathe naturally.

If the patient does not take chloroform well, change to ether.

The best method of giving chloroform is to commence with a drop a second on an Esmarch inhaler, which is brought at once close to the face. This is about as quick as any other method, and is positively the safest. By using the drop method the anesthetist will be very seldom required to use means to resuscitate.

Chloroform should not be used at night operations. This caution does not apply when the incandescent electric light is employed. Use chloroform when ether has failed, or when there is a record of deleterious effects during a previous anesthesia with ether. Ether is contraindicated in bronchial and tracheal catarrh, constant coughing with asphyxia, irritation of the air-passages, violent continuous nausea, and in marked kidney disease, when chloroform or a local anesthetic must be used. Chloroform or ether should not be used in exceptional instances (see Local Anesthesia).

Ether is best given by the drop method (Prince) somewhat the same as chloroform, except that the Esmarch inhaler should be covered with twice the thickness of gauze covering used for chloroform, and the drops are allowed to fall more frequently on the mask—two or three drops to the second till the patient is under, when a drop in a second or two seconds is sufficient to maintain perfect anesthesia. As a rule inject hypodermically fifteen minutes before beginning anesthesia one-quarter of a grain of morphine. By this means less ether is required, and a perfectly satisfactory anesthesia is obtained.

Anesthesia and Taxis.—Simple taxis having been tried, except under those conditions known as contraindicating it, and having been found unsuccessful, it should be resorted to under general anesthesia, preferably ether, except in those cases where a general anesthetic cannot be used without danger. In the latter instances operate at once, using local anesthesia. Before using taxis under anesthesia, make preparations for operation, so that in the event of failure to reduce the protrusion herniectomy and radical operation can be done at once. By this means time is saved, the danger lessened, and the patient avoids a second anesthesia.

THE TREATMENT OF GONORRHEA IN WOMEN, WITH SPECIAL REFERENCE TO URETHRITIS.*

By Geo. Eretly Shormaner, M.D.,
Gynecologist to the Methodist Hospital, Philadelphia.

The importance of this subject is very great, because of its well known frequency even among the innocent, and because it is responsible for a vast amount of suffering. When untreated or imperfectly treated it becomes in the unchaste a long-standing evil in the community, while among those leading an upright life it becomes one of the common causes of sterility or of postpuerperal disorders. In the form of salpingitis it may entail lifelong suffering from recurrent attacks, accompanied by localized peritonitis. It frequently leads to capital mutilating operations, endured as a choice of evils after prolonged ill health.

Admitting the unpleasant character of the whole matter, and the fact that many of us do not care to cultivate this class of practice, it yet remains that no physician who accepts obstetrical or gynecological patients can escape meeting the disease, even among his best clients. It follows therefore that he cannot escape the responsibility for its proper treatment.

The results of the management of the disease are often unsatisfactory. Definite cure may be very hard to obtain. This can hardly be better shown than by the side-lights in the recent controversy† between Neisser, a world-renowned authority, and Behrens, who has unlimited experience through his official position.

*Read before the Section on General Surgery, College of Physicians, Philadelphia, Oct. 12, 1899.
†Botsch, klinische Wochenchrift 1898, No. 6 and 8.
connection with the regulation of prostitution in Berlin. The difference arose owing to the skepticism of Behrens as to the value of bacterial examinations in determining whether or not the disease is cured, and as to the usefulness of germicidal methods of treatment. He thinks he has given them a fair trial, and returns with some disappointment to clinical diagnosis and to general plans of treatment, the latter including, in the male, rest, ice, and mild astringents. Such a controversy could not arise were the results of treatment giving general satisfaction. They are, however, better now than formerly, when the disease was considered to be chiefly vaginal, and when vaginal injections were relied upon.

Two points must be prominently kept in mind in considering the matter of treatment. The first is that the disease is a formidable one to eradicate thoroughly, requiring the physician to be alert and in earnest. The second point is that the seats of infection are various, not the same in every case, and some of them are out of reach of treatment which consists only of balsams by the mouth and the vaginal douche.

The disease therefore must be attacked, sooner or later, in its various strongholds, which are, besides the vulva, the urethra and its long tubular glands, the vullovaginal glands of Bartholin, the cervical canal, and lastly the body of the uterus and the tubes, should they become invaded. The difficulty in curing the disease justifies the demand for the most important part of the treatment in the acute stage, namely, rest.

Rest in bed during the continuance of the acute symptoms is, fortunately, much easier to secure in important cases in women than in men, as they find it easier to account for an illness without exciting suspicion. Attention to the bowels and to diet must be directed along well known lines.

No treatment can be successful which fails to take into account the important fact that there are several points of infection. For example, if the vulva and the cervix were freed from disease and no attention were paid to a urethritis, the case would remain uncured. If no disease remains in the urethra the patient may continue to be permanently infected, if on either side of the vestibule the gland of Bartholin pours out through its infected duct a quantity of bacteria-laden fluid every time pressure is made, or the function of the part is aroused. It is owing to the difficulty in reaching thoroughly the various seats of infection that the best directed treatment may be tedious or disappointing, and for a similar reason the routine treatment of the past has never been satisfactory.

There is quite a variety of opinion as to the frequency of the involvement in the various localities. It is now known that primary gonorrhea of the vagina in the adult is rare, and some doubt its existence. Infection of the urethra probably occurs in nearly all acute cases, though its intensity may be relatively slight, and the duration short.

Horand,* in examining over 5000 women, chiefly prostitutes, found the urethra to be the most frequent seat of the disease. Wertheim in one series of examinations found it involved in every case. The next most favored locality is the endometrium of the vaginal portion of the cervix uteri. Bumm† studied fifty-three cases from the very beginning through five months, and found infection here in seventy-five per cent of the individuals, while the uterine cavity became involved in only fifteen per cent, and the tubes in three and a half per cent. In the acute stages no treatment can be wisely directed to these special localities. The patient should be in bed. Great attention should be paid to external cleanliness, to the cleansing of the hands, and the immediate destruction of all soiled dressings. There should be frequent mopping of the parts with weak carboic acid, strong boric acid, or creolin or permanganate solutions. Three or more times a day the same solution may be used in a copious hot vaginal douche. If greatly swollen and inflamed, the lesser and greater labia may be separated by a thin layer of lint or cotton wet with dilute leadwater containing opium. Water should be taken freely by the mouth, and such medicines as will keep the urine as aseptic as possible (salol or boric acid) and will serve to allay bladder and urethral irritation. As soon as the tenderness has subsided sufficiently to allow the use of an instrument, treatment must be directed to the several localities involved. The most important of these is the urethra. Cleansing injections of boric acid solution may or may not be used. They should be followed by suppositories of ichthyol or iodoform inserted into the canal.

At the International Congress at Rome in

* Lyon Medical, lix, 241.
† Frauenarzt, 1891, vi, 345.
1894 Jullien* strongly recommended ichthylol and glycerin 1 to 5 or 1 to 10. He applies it upon a wire carefully wrapped with cotton for three inches. After insertion of this into the urethral canal, pressure from the vagina will distribute the material into the urethral folds and depressions.

Skene (Diseases of Women, page 823) says that the most efficient treatment of acute urethritis is to wash out the urethra with a fluted reflux catheter two or three times a day, and then introduce a suppository of iodoform in cocoa butter or of bismuth subnitrate in cocoa butter. After the disease has assumed a chronic form, as it frequently has done when first seen by the physician, direct applications through the urethral speculum are of very great service. Nitrate of silver 1 to 5 per cent may be applied under direct vision to the reddened and inflamed or ulcerated patches, which will be found usually at one end or the other of the canal, rather than in the middle. Injection methods may be utilized as in the male, but care must be taken not to inject too much fluid at once, so as not to enter the bladder. The average urethra is only an inch and three-eighths long, and holds only about fifteen drops of fluid when not distended. Skene uses a pipette which goes over the meatus and not into it. Additional safety for the bladder may be secured by using an injection only when the bladder is full, so that any fluid which passes into it may be at once freely diluted. When the neck of the bladder is also diseased a very weak silver nitrate solution, one grain to the ounce, may be used in sufficient quantity to pass through the urethra, but as this is uncertain and may carry discharges with it, a better plan is to make direct applications through the speculum.

Along the floor of the urethra lie two tubular glands, from a half to three-quarters of an inch in length. Their orifices lie just within the meatus. When these once become thoroughly infected they may remain so for months, in spite of all treatment which does not involve direct applications with a probe to their interior. If nitrate of silver so used is not effective, it may be necessary to slit them up. Treatment must be continued until the gonococcus can no longer be found in the discharges. Before a case can be pronounced cured, however, all the chief seats of infection must be shown to be free from the organism if this method be relied upon. This becomes rather a tedious process. It is hardly necessary in these times to insist that throughout the treatment all instruments used must be carefully boiled.

In the use of the urethral speculum, even in chronic cases, much gentleness must be used. It is easy to irritate or to abrade the mucous membrane to the point of bleeding. Only small sizes (8 millimeters, or at most 9 millimeters) should be used. As frequently sold, these instruments have sharp edges at the vesical end, which are very objectionable and scrape badly after the obturator is withdrawn.

To the vulvovaginal glands no direct treatment can be advantageously applied in the acute or subacute stages. Injection of the ducts has been recommended later. If recurrent abscesses form in chronic cases the whole gland must be dissected out. If all of the sac wall is secured primary union will follow catgut suturing, which obliterates the pocket. Otherwise a troublesome gauze packing must be used till the pit closes from below.

The infected cervix must be treated by the careful removal of the tenacious discharge by cotton-covered forceps, followed by the topical use of ichthylol, protargol, nitrate of silver, or other appropriate solution. The probe must never be introduced into the uterine cavity unless this is already involved. Indeed, a probe should never be introduced into any ureter canal without strong reason. It is normally sterile, and should be allowed to remain so.

A copious vaginal cleansing douche is to be given before the treatment above outlined is used. Then after the cervix and urethra have been treated, ichthylol and glycerin 1 to 10 should be liberally applied, and a light vaginal pack of borated or iodoform gauze should be inserted to keep the surfaces apart. This pack can be best applied in the knee-chest posture, using the Sims speculum, as in no other position is so little pain caused, and none so thoroughly balloons the vagina, at the same time soothing out its folds.

In this brief paper there is no opportunity for the discussion of the treatment of the conditions which result from infection of the uterine mucosa or of the tubes and peritoneum.

THE SYMPOSIUM ON Puerperal Eclampsia.

In this issue of the Therapeutic Gazette we have published a symposium on this important subject that cannot fail to prove useful and instructive to our readers. The contributors are men whose practical experience and study have well qualified them for the preparation of what they have written, and their teachings are well worthy of attention. The fact that eclampsia is so largely a preventable disease and yet is constantly met with evidence that more care should be paid to the subject than is generally done.

THE MODERN TEACHING OF THERAPEUTICS.

While there are many persons, in and out of the medical profession, who are under the impression that our methods of treating disease have not advanced as rapidly as have other departments of medical science, those who have made even a superficial study of the subject thoroughly appreciate the fact that this is untrue and that therapeutics has not only advanced, hand in hand with collateral departments of medicine, but in some instances has maintained the lead which it acquired before these various departments possessed the importance that they do today. Thus it is, without doubt, a fact that a number of conditions and diseases were, and are, successfully treated without the physician being enlightened in regard to their etiology and pathology, and while very often the application of the remedy is not followed by such sudden and brilliant results as follow the application of the knife, the results when obtained are very frequently more lasting and certain.

As a matter of fact, there is no department of medicine which has shown an activity similar to that of therapeutics, and while it is undoubtedly true that much of the literature dealing with the treatment of disease which has been published within the last few years is fleeting in its value and even utterly valueless, a very large amount of useful material has been winnowed out and separated from the tares. It is only when one stops to compare his therapeutic possibilities of today with those of fifteen or twenty years ago that he appreciates the great advances which have been made. These remarks are made, not because we believe in therapeutic optimism, but because on the other hand we do not believe in therapeutic pessimism. We all must recognize the fact that undue enthusiasm is out of place, but also that it is ill-fitting for us to feel discouraged because we are not able to remedy conditions which possibly are irretrievable, either because they cannot be cured or relieved by reason of their very nature, or because our knowledge concerning the disease itself is as yet so crude that rational methods cannot be introduced.

With the improvements which have been made in the methods of treating various diseases there has been an equal improvement in the method of teaching that branch which for years has been known in the roster of the medical schools as "Materia Medica and Therapeutics." Perhaps the majority of practitioners to-day look back upon the lectures which they heard under the title of "materia medica" as being the driest and most uninteresting of their medical curriculum, and increasing experience has confirmed them in the belief that much of the information which was presented for their mental digestion in
these lectures has proved itself utterly useless to them in their professional career. The day is not long passed when the professor of materia medica lectured behind numerous bottles and glass jars containing dry and wet materia medica specimens, and took more pains to impress upon his pupils that kino was the inspissated juice of the *Pterocarpus Marsupium* than he did to tell them that kino, in the form of a tincture, was sometimes employed as a vegetable astringent in cases of diarrhea. Nor is it long since the professor of materia medica grew rapturous over his description of the difference between the appearance of the *Rosa Gallica* and *Rosa Centifolia*. The day in which this method of teaching was adhered to is not long passed in the matter of time, but surely it is of the past in the sense of actual progress.

At the present time the demands which are made upon the progressive teacher of therapeutics and materia medica force him to devote almost no time whatever to the description of the botanical and geological origin of the various medicinal substances, and he really ceases to lecture upon these things in view of the immense amount of more valuable information which he can impart to his class, and because under present conditions a physician no longer has occasion to handle crude drugs or to prepare pharmaceutical products from them, all such manipulation being done by manufacturing chemists and competent pharmacists. It is very much more important to-day that the doctor should know the appearance, taste, and other qualities of tincture of digitalis than that he should know the appearance of the digitalis leaf, and still more important that he should have clear and definite ideas as to the therapeutic value of digitalis, its contraindications, and the conditions which its administration will best remedy.

It is of course true, on the other hand, that a physician who knows medical botany has the advantage of a liberal education over and above what might be called a practical medical education, and if an individual has a true bent in this line, or the time and opportunity to obtain this learning, it goes without saying that as all learning of every kind is advantageous, so is a knowledge of medical botany of value. It is not, however, of value to the practicing physician of the present decade except as an accomplishment. In the belief of the writer of this editorial, the time is not far distant when further modifications than those already made in the methods of teaching materia medica and therapeutics will take place.

We are confident that the proper method of teaching therapeutics is not from the drug to the disease, but rather from the disease to the drug. In the sick-room the doctor is not placed with a series of drugs of different kinds in front of him, but he has before him a patient suffering from a given complaint, and after making his diagnosis as to the condition before him, he then must pick out from his mental array of drugs that remedy or remedies which he knows are indicated in the case.

In other words, the doctor should be taught not so much that aconite is indicated in such and such diseases, but that such and such diseases indicate the employment of aconite, and then his teaching will be in the same line as his practical experience which follows it. We believe that every professor of therapeutics should devote himself to a thorough consideration of the clinical application of the remedies upon which he lectures, after having first, it may be, thoroughly explained to his pupils the so-called physiological action of the remedies of which he is speaking. We also believe that whenever possible he should illustrate any didactic lectures which he may give by subsequent medical bedside clinics in which the practical application of the various drugs upon which he has lectured is demonstrated as clearly as possible to his class. Again, it is possible by this means to render the course of materia medica and therapeutics one of the most interesting and practically useful courses in the medical curriculum, and very often facts in regard to the physiological action of a remedy can be more readily impressed upon the mind of the student by considering such physiological action, in juxtaposition with a consideration of the treatment of disease, than can be done if the physiological action is first described and then the clinical application is given without there being any connecting link between them.

The student and the physician of to-day, not only in the department of therapeutics, but in nearly all the departments of medicine, is left too much to the difficult task of joining together scientific facts which he may be taught with clinical conditions which may be pointed out to him. On the one hand he receives the results of valuable scientific research; on the other he sees what apparently is too often mere empiricism; and the teacher
who successfully points out the fact that these two masses of information, so to speak, are really joined together, performs his function more successfully than he who does not. Indeed, we believe that it is the function of the teacher of to-day, in therapeutics in particular, to sift the useful facts of science from the useless, but nevertheless interesting, facts of science in order that his pupils may have presented to them for their mental digestion only such particles of mental pabulum as they need for the proper growth of their medical knowledge. It is well enough for them to take up abstract and difficult scientific propositions after they have obtained their degree. Too often at the present time, in the enthusiasm of teaching, the original investigator is tempted to digress from the hard practical facts of every-day medicine and lead his students into by-paths which, while they may be roads to knowledge, are nevertheless "side-tracks" to him who as yet must travel the straight and what may be called the fundamental road of medicine. We feel confident that most of the practitioners of to-day will agree with us in this statement of our views as to the proper means by which this, perhaps the most important, branch of the medical curriculum is taught.

THE RELATIONSHIP BETWEEN THE OVARY AND MAMMARY GLAND.

With the advances which have been made within the last few years in the use of various glands in therapeutics, it has been claimed by certain physicians that the employment of ovarian extract on the one hand, or of mammary gland on the other, was capable of producing certain influences upon these organs, the mammary gland affecting the ovary, and vice versa.

As long ago as May, 1896, Beatson, of Glasgow, exhibited an extraordinary case in which an inoperable and recurrent cancer of the breast had disappeared apparently as a result of the removal of both ovaries and the administration of thyroid extract; and after him, Stanley Boyd, of London, performed oophorectomy alone, without giving any thyroid, to determine what effect this operation would have upon mammary carcinoma.

In the British Medical Journal of September 30, 1899, Boyd records the results which he has obtained, both with and without the use of thyroid, after oophorectomy in his first and later cases. He believes, notwithstanding the fact that he has employed thyroid gland in addition to the ablation of the ovary, that it cannot be essential, because as great success can be obtained without it as with it, and he does not believe that there is the slightest evidence that the thyroid gland exercises a favorable influence in cancer. It is true that Page and Bishop about eighteen months ago recorded a case in which the administration of thyroid to a woman with mammary cancer seemed to produce an arrest of the growth, but notwithstanding this single individual instance he has little confidence in the value of thyroid under these circumstances. As the result of a study of his cases he has reached the following conclusions:

1. The ovaries removed have usually seemed healthy.

2. That results are not uniform: some are successful, some partially so, some quite unsuccessful. Non-success seems to be connected with: (1) presence of much cancer; (2) affection of bones and viscera; (3) long cessation of menstruation, or rather with the ovarian changes indicated by this; and (4) cachexia. But there is something else required to account for some of the failures.

3. As to Type of Disease.—No really acute case has shown the maximum of benefit; but for six months marked improvement occurred in his second case, aged thirty-seven, in whom the total known duration of the disease was two and a half to three years. The most successful cases were of four to seven years' growth up to the oophorectomy.

4. Age.—The extreme ages of the patients were: thirty-three in Beatson's No. 1; forty-nine in Herman's No. 2.

5. Relation to Menopause.—This patient of Herman's had for six months been irregular, and for three months had seen nothing. This is the only case known to him of improvement from oophorectomy apparently after the menopause.

6. Influence of Seat of Secondary Nodules.—Growth starting from mammary epithelium are not uniformly affected by oophorectomy. Speaking generally, those in the skin and subcutaneous tissue are most readily affected by oophorectomy; then infected glands, then growths in the breast itself. Muscle nodules grow slowly, and he knows of no proof that growths in bones or viscera are affected at all. Even neighboring growth in the same tissue do not disappear at the same rate.

7. Duration of Action.—Sufficient time has not yet elapsed to determine whether any of
these disappearances of cancer may be permanent. His first case showed no sign of relapse when he saw her twenty-eight months after oophorectomy. In Dr. Beatson's case relapse began at twenty-five months. When relapse occurs there is a great tendency for nodules to reappear upon old sites, as if some cells had remained dormant at these spots. In some cases—for example, Dr. Beatson's—the recurrences have developed very slowly, as if held in check or resisted by the tissues; and Boyd thinks he has noticed the same retarding influence in the case of growths which have not disappeared after an oophorectomy. But it is, of course, impossible to be certain of this.

8. Mode of Disappearance.—Dr. Beatson showed that diminished vascularity of cancer nodules, coupled with loss of pain, was the earliest effect of oophorectomy. By excising shrinking nodules he demonstrated that they were undergoing rapid fatty degeneration.

9. Effect upon Cancers Other than Mammary.—Uterine cancer has in several instances been treated by oophorectomy. Diminution of hemorrhage and of sepsis have been the most favorable results obtained. And yet one would have supposed that the association of the ovary and uterus was closer than that of the ovary and breast. So far as Boyd can ascertain from the scanty material at present available, these are the chief points in the case which he has to lay before us. The practical importance of the matter is self-evident. He thinks we will agree with him that in some cases of recurrent cancer of the breast removal of the ovaries induces atrophy of the cancerous growth. The main question he wishes to submit to us is how this may be brought about. He would particularly ask for suggestions as to the experimental solution of the problem. There is hardly anything in the abdomen which is not removed, intentionally or unintentionally, nowadays; and there can be no doubt that a careful noting of results of operations would convert many of them into useful experiments.

His own working hypothesis has been that the internal secretion of the ovary probably exercises an important influence upon all the cells of the body; that this internal secretion may vary in quality, pathologically if not physiologically; that when varied in some unknown way the ovarian secretion favors the growth—possibly even the action of the cause—of cancer, influencing either the invading epithelium or the resisting mesoblastic tissues. The removal of ovaries of which the secretion is thus faulty would leave the tissues unhampered, and might turn the scale in their favor, at least for a time. On the other hand, the removal of ovaries secreting normally would have no effect upon the cancer present.

It is interesting to note that a prominent member of the medical profession in this country, Prof. E. E. Montgomery, of Philadelphia, has recently published an interesting paper in which there is a consideration of this line of treatment. Collateral information in regard to this subject is also embodied in an interesting and brief article by Routh in the British Medical Journal of September 30, 1899, which will be found in our Progress columns of the current month.

SUITABLE CASES FOR HEALTH RESORTS.

Several months ago we called attention, editorially, to a statement made in the Denver Medical Times concerning the rules which should govern physicians who are about to send patients to health resorts for pulmonary tuberculosis. In that editorial we pointed out the necessity of sending only those cases in which the disease was developed to so slight a degree that there was a strong probability of recovery under proper climatic influences, and we endeavored to emphasize the fact that it is nothing less than cruel to send a patient to a health resort when his pulmonary condition is such that recovery is impossible, the only result being that he spends his remaining energy and funds in a futile struggle for the unattainable. Our attention has once more been called to these facts by an interesting article which has appeared in a recent number of the Medical News by Dr. Cobb, a past assistant surgeon in the United States Marine Hospital Service. In the course of this article, speaking of the arid region of the United States in the treatment of pulmonary tuberculosis, Cobb calls attention to the fact that it is absolutely necessary when tubercular patients go to health resorts that these places should be provided with suitable comforts for an invalid, both in the way of beds and food, and should be surrounded by certain hygienic conditions. Then he calls attention to another point often ignored, namely, that even when a patient goes to a place where the mean temperature is fairly low, he should be provided with warm clothing, since the "mean temperature" does not in reality represent
the atmospheric conditions to which he will be exposed. In many health resorts the temperature in the sun is quite high and in the shade quite low, and there are very great variations between the temperature of the day and night.

Again, he points out that in many of the smaller resorts for consumptives suitable disinfection is not carried out, and he noticed in a number of instances in his experience that the bedding frequently had the odor of perspiration which is so peculiar to consumptives; that the beds were supplied with cotton quilts which never were washed; and that not infrequently quantities of dry sputum were found upon such quilts. To use Cobb's words: "One should never believe that the room offered to you has been properly disinfected or that a consumptive has not preceded you." It is perfectly possible, as he says, for a patient to visit such a resort with a mild infection, and to have superimposed upon it a more malignant one. We are quite certain that frequently patients are exposed to this possibility, and in a given case we would insist that the room be carefully disinfected before it is occupied, even if it is true that a tubercular patient has not occupied it recently. This disinfection can do no harm, and may do much good.

THE USE OF SALINE TRANSFUSION FOR BURNS AND SHOCK.

It is not many years since the employment of ordinary saline solutions, hypodermically or intravenously, was first urged upon the general practitioner by those who had had experience in this line of treatment. Each year that has passed since these early recommendations has served to emphasize the great value of this therapeutic measure, and our columns have again and again contained reports of cases of infectious diseases, of cases of toxemia like puerperal eclampsia, uremia, and diabetic coma, in which excellent results have followed this method of treatment.

In the spring of 1898 the writer of this editorial also called attention to the results which had been obtained by Tommaselli in the treatment of severe burns by hypodermoclysis and intravenous injections. Tommaselli believed, from clinical observation and experiment, that a large part of the lethal influence of burns depended upon toxemia, and on putting his belief to the practical test he found that artificial saline injections saved life. So, too, in this country Bardeen, as a result of a histological study of the tissues of several children who had died from burns, came to the conclusion that toxemia was an important factor in causing death, and his results indorsed the proposition of Tommaselli in regard to this method of treatment. Even if the toxemic condition is not directly improved by saline injections into the subcutaneous tissues or veins, there is still another one in which this method of treatment may be of great good, in that surgical shock is nearly always present as a result of severe burns and scalds, and we have reasons, both theoretical and practical, for the belief that in shock a condition of profound relaxation of the blood-vessels exists, so that arterial pressure is very low and the vital centers are not properly supplied with blood.

While we know that intravenous injection does not necessarily raise blood-pressure, we also know that this method of treatment is capable of readjusting the circulation to such an extent that the evil manifestations of vasomotor paralysis are set aside. It seems to us, therefore, that in treating cases of severe burns or scalds, this method of procedure should not be ignored, but should be actively employed, since it can do no harm, and may do much good.

THE USE OF COCILLÄNS AS AN EXPECTORANT.

From time to time new drugs derived from the mineral or vegetable kingdom are brought before the medical profession, some of them quickly obtaining a reputation which they do not deserve, and then speedily losing their fictitious repute, while others climb more slowly into professional favor and remain popular with a certain number of practitioners. Among the latter class may be mentioned the drug cocillän, which was first brought to the attention of the profession as a medicament by Professor Rusby, the well known botanist of New York, who, in a visit to Bolivia in 1886, found that this plant was used for expectorant purposes. In very full doses it, like ipecac, produces emesis. It is evident from the reports which have been made upon it, notably by Stewart and Wilcox, that the drug may be employed as a stimulating expectorant for the purpose of aiding the patient in getting rid of bronchial secretion, and that under these circumstances it is capable of producing very
excellent results. As this substance has not received the wide application which its therapeutic properties would seem to deserve, we have called attention to it in order that it may be more largely tried, and that more definite conclusions as to its exact value may be reached.

THE PREPARATION OF CATGUT FOR SURGICAL PURPOSES.

The lack of uniformity in the preparation of catgut for surgical operations attests more strongly than could any other single circumstance the difficulty attendant upon the producing of strong, elastic catgut which is able to take a close knot without breaking and to hold it, and which, at the same time, is absolutely sterile. Although the gut which is sold in commerce is sometimes sterile, owing to the processes to which it has been subject during the course of its manufacture it generally contains germs. As a rule it is non-pathogenic, but exceptionally, as in the case of animals perishing of anthrax, both the germs and spores of this virulent disease are found in the gut, and are capable of cultivation from it.

By far the most complete and satisfactory study of catgut preparation is that contributed by Minervini in the September number of the *Deutsche Zeitschrift für Chirurgie*. This author has investigated not only the bacterial life of unprepared gut and that which has been subject to practically all of the many well recognized methods of sterilization, but has tested the tensile strength of the gut before and after preparation, has investigated its brittleness and its capacity for taking knots, and notes the effects of the various reagents employed upon the permanency of the gut in the tissues.

First, in regard to the tensile strength of the gut, he shows that alcohol, even as weak as seventy-five per cent, does not materially change it, but that a weaker solution softens the gut and greatly lessens its strength. Absolute alcohol makes the gut so hard and stiff that it does not lend itself readily to being tied. Chloroform, ether, oil of turpentine, and xylol have similar effects. Glycerin moderately weakens the gut. Fatty substances, at ordinary temperatures, such as olive oil, castor oil, or oil of juniper, make the gut somewhat more elastic than in its dry state and do not lessen its strength. Moreover, the knots are readily fixed and held. Formalin, in one-, five-, and ten-per-cent solutions, diminishes the tensile strength, but not very greatly, and gut prepared in this manner can be easily tied. Chronic acid in strong solution lessens the strength of the gut; in strengths of one-half to two per cent it diminishes the strength, but leaves it in excellent shape for ligatures. The best solution is one-half of one per cent.

The tabulations as to the effect of heat upon the gut are extremely instructive. Thus, boiling alcohol does not lessen the strength of the gut but makes it so stiff that knots are not readily tied. A weak solution of alcohol markedly diminishes the strength; the same may be said of boiling ether and chloroform. Turpentine, xylol, and other media which boil above 100° C. markedly weaken the gut, but if the water has been previously removed, this weakening effect is far less marked. Gut which was laid in four-per-cent formalin solution for twenty-four hours, then in running water for twenty-four hours, and finally boiled fifteen minutes, was much weaker than the raw gut; nevertheless it still preserved sufficient strength for use, excepting the finest sizes. Gut thus prepared is easily tied, and the knots do not exhibit a tendency to loosen.

A further series of investigations was conducted with the idea of determining the effect upon the strength of the gut of heat under pressure.

As a result of these experiments, Minervini concludes that catgut can withstand dry heat up to 150° C. without alteration—at or above 160° C. marked alteration occurs; that water always weakens the gut, softening and swelling it at normal temperatures, and completely disorganizing it at the boiling temperature; that this injurious action of water upon the gut may be prevented by the influence of chemicals—namely, formalin and chronic acid—but that gut thus treated is still injuriously affected by water, but to a much less degree. Chemicals which boil at a temperature lower than 100° C. do not alter the gut provided they contain no water. In different fluids which boil at a temperature higher than 100° C., such as xylol, cumol, etc., provided the gut has been entirely freed from water, it is not materially altered until the temperature reaches 150° to 160° C. Above this temperature profound alterations occur.

As to the efficiency of the various antiseptics in accomplishing absolute sterilization of the gut, alcohol, ether, chloroform, and carbolic acid solutions at the ordinary tempera-
ture were found absolutely unreliable. Oil of juniper rendered gut infected with staphylococcus germ-free after three days. To destroy the anthrax bacilli, however, required thirty days. Bichloride solutions, 1:1000, in water are efficient both against anthrax and pus germs in one hour. Solutions of similar strength in alcohol or ether require twenty-four hours to exert as marked an effect. A one-per-cent watery solution of formalin destroyed the staphylococcus in six hours, and twenty-four hours' exposure to a four-per-cent solution was required to destroy the anthrax bacilli. One-half-per-cent solution of chromic acid destroyed the staphylococcus in one hour, and one-per-cent solution was required for six hours against the anthrax bacilli.

In oil of juniper heated to 130° C. the infected pieces of gut were entirely sterilized in thirty minutes. Carbolic solutions in alcohol were found entirely unsatisfactory. Catgut soaked in a four-per-cent formalin solution for twenty-four hours, then in flowing water for twenty-four hours, and finally boiled in distilled water for fifteen minutes, was absolutely sterile, as was also the gut subjected to the same process with the exception that chromic acid, one-half per cent, was substituted for the formalin.

The author concludes from his investigations as to the sterility of catgut that whether the heat be dry or conveyed by means of alcohol, ether, chloroform, etc., exercised under normal pressure, the germs and their spores are only destroyed when a temperature of 140° to 150° C. is reached and is maintained for some hours. Since at about this temperature alterations of the gut occur, the aseptic preparation of the gut is not practicable.

Those methods which depend upon the action of carbolic acid or of the aniline colors are always unsatisfactory.

If properly employed, and for a sufficient length of time, sublimate, formalin, chromic acid, and oil of juniper secure absolute sterility.

An investigation into the absorbability of the gut showed that the commonly accepted ideas upon this subject are erroneous, in dogs at least. The gut was found after four months unabsorbed in the tissues. Gut prepared by dry heat, oil of juniper, and formalin is much more rapidly absorbed than that subjected to sublimate and chromic acid methods. It is clearly shown that the preparation of a strong and yet absolutely sterile gut is an extremely difficult matter unless antiseptics are employed, and that these antiseptics always retard the absorption of the gut.

Minervini, as a result of his elaborate research, holds that surgeons who use but one ligature material should prefer silk; that those who wish to employ both materials should use catgut for sutures of the mucous membrane, particularly in deep cavities difficult of access; that catgut should also be preferred to silk in sutures of the skin.

Though most surgeons will not agree with this contention, holding that even if catgut be absorbed slowly its ultimate disappearance is to be preferred to leaving a foreign body permanently at the site of the wound, they will, if they believe in the accuracy of Minervini's observations, and these are in accord with those of the majority of observers who have studied this subject, adopt either the oil of juniper, formalin, chromic acid, or heat method of preparing their gut.

**FRACTURES OF THE FEMORAL NECK.**

Although many treatments have been suggested as efficient in procuring union after fracture of the neck of the femur, hospital records and the wards of all large charitable institutions will abundantly prove that none of these methods are successful in certainly a very large number of cases. Senn advocated for intracapsular fracture the application of a plaster-of-Paris cast provided with a pad and screw, by means of which the bones, once having been brought into position by traction, could be so held until union took place. Though his paper on this subject, with reports of the cases successfully treated, appeared six or eight years ago, his method has, at the best, received a very limited trial, nor is there any evidence to show that it is generally successful. The same may be said of all the methods proposed. Hence, when Ruth reports in the *Journal of the American Medical Association* seventeen cases of unquestioned fracture of the femoral neck, occurring in persons ranging from twenty-five years to almost the extreme limits of age, treated by Maxwell, Kinnaman, Jenkins, Fagers, Coulter, and Ruth, and notes that in fifteen of these union was obtained with useful limbs, whilst the only failures to secure union were in two cases that absolutely refused to have the treatment carried out, his communication is entitled to consideration and respect.
After the injury he adjusted the fragments by flexing the thigh upon the abdomen and relaxing the psoas and the iliacus, bringing them above the fracture line, thereby preventing them from being permanently caught between the fragments. This position also relaxes nearly all of the external rotators. Then vertical traction is made of the shaft of the femur, which now stands at right angles to the trunk while a moderate elevation is being maintained. Next the leg is abducted to the normal line, and extension is made in the long axis of the trunk while an assistant makes traction one-half to two-thirds as strong upward, slightly outward and forward from the upper end of the femoral shaft. These manipulations should be made by firm, steady traction, not by jerks, which is to be made continuous by Buck’s extension, with a weight of from ten to twenty pounds. Binders’ board should then be molded to the upper inner aspect of the thigh, over which a band of muslin four to six inches wide should pass outward and slightly upward and sufficiently forward that the weight from the pulley shall overcome the internal pull of all the rotators and adductors, and at the same time raise the lower fragment to its normal level. The weight on this lateral pulley will be from five to fifteen pounds. The side of the bed corresponding to the injured side of the patient must be raised enough to prevent the individual from being drawn out of position by the lateral pulley.

In the report of cases it is specifically stated in at least three instances that the fracture was intracapsular; in eight others it was at the femoral neck, and therefore must have been intracapsular.

If in the hands of the general practitioner this modification of the customary treatment produces results in any way comparable to those reported, Ruth will have done a great service in lessening the heavy burdens of a crippled old age.

POSTANESTHETIC PARALYSIS.

It exceptionally happens after a general anesthetic has been given, quite aside from the form of surgical intervention which may have been required, that when consciousness is regained there will have developed a paralysis which, at least by the patient and his friends, is likely to be attributed to the ether or chloroform or whatever agent has been administered to occasion unconsciousness. Such palsies are classified by Mally, who has contributed an excellent paper on postanesthetic paralysis to the Revue de Chirurgie, No. 7, 1899, as central, hysterical, peripheral, and reflex.

The central palsies follow directly upon the anesthesia, and are due with few exceptions to cerebral hemorrhage. It would not be unreasonable to suppose that such an accident—i.e., apoplexy—would be a fairly common sequel or accompaniment of an anesthetic, since a large number of surgical patients are by vascular degeneration ripe for hemorrhage from even the most trifling causes. As a matter of fact, however, apoplexy during anesthesia is extremely rare, hence may fairly be considered purely accidental and in no way attributable to the anesthetic agent used.

As to the postanesthetic hysterical paralysis, this also is extremely rare, and is to be attributed rather to the moral shock than to any action of the anesthetic employed.

Peripheral palsies are the most frequent and important of the various groups. The commonest of these is a palsy of the upper branches of the brachial plexus, and this is generally caused by the elevation of the arms such as occurs in the Trendelenburg position; for with the arms thus elevated there is a drag upon the roots of the plexus, and particularly the upper ones, and these are, moreover, put at a sharper angle than the ones which lie below, this angling occurring at the transverse vertebral processes and being caused by the indirect pressure of the latter. It is noted that the deltoid is the muscle most commonly involved, though the supra- and the infraspinatus and other muscles are often implicated. The type of the palsy is characteristic—i.e., it corresponds to the pressure type. The prognosis is good, and recovery is the rule. Cases are reported in which the radial, cubital, and anterior tibial nerves were paralyzed, probably from pressure because of faulty position. There is no evidence to show that these peripheral palsies are in any way related to the anesthesia.

Reflex palsies are extremely rare, and are characterized by an exaggeration of the reflexes, moderate but persistent atrophy, and a diminution in electric excitability. They are comparable to the palsies which commonly succeed traumatisms of joints. Their occurrence after anesthesia is probably purely accidental.

It would appear, then, that the only form
of postanesthetic palsy which is avoidable is that of the peripheral type, which is always due to pressure. It should be avoided by guarding against putting the arms in the position of forced elevation and by providing against too long continuous' pressure, as by an Esmarch tube, or the resting of a limb over the edge of a table. The curative treatment consists in the use of electricity, unless there are signs of degenerative atrophy. Passive motion and massage should also be employed.

Reports on Therapeutic Progress

METHYLENE BLUE AS A SEDATIVE IN INSANITY.

The history of the use of methylene blue in general therapeutics is similar in many respects to that of other aniline compounds. Early reports, backed by commercial interests, were indicative of its value as a general panacea for many of the ills of the flesh, but of recent years it has found an established though restricted field in a limited number of affections. Its value in malaria admits of little doubt, and in migraine and other nervous affections evidence is slowly accumulating that will give it a recognized position among the hypnotics.

Recent studies by P. Bodoni, of the University of Genoa (Klinisch - therapeutische Wochenschrift, No. 21, 1899, p. 666), seem to show its wide applicability as a sedative in excited mental states. He reports fourteen cases in which the remedy was tried; these included such conditions as simple acute mania, mania with furor, periodic mania, chronic mania, and the mania of chronic alcoholism, periodic melancholia, paranoia with delirium, hystero-epilepsy, and puerperal mania. In all of these cases the remedy was administered by hypodermic injection into the glutal muscles, in amounts varying from one to one and one-half grains. Its sedative action became manifest within from three to six hours and usually persisted a day, or, in some of the cases, even for three to four days. The quieting action was not attended by any narcotic effect, and there were no unpleasant after symptoms observed.

The cause for its action is not definitely understood. By analogy, bearing in mind the use of this substance in technical microscopv by reason of its affinity for nerve tissue (methods of Ehrlich, Nissl, etc.), it would appear that it has a specific action on these tissues during life. This, however, has been denied by some observers, who are inclined to class the drug with the blood poisons, acetanilid, etc., and thus explain its pharmacological action. The author believes that it should take its place with others of the hypnotics, such as chloral, amylenydrate, trional, and even hyoscyamus. — Medical News, Sept. 9, 1899.

THE USE OF QUININE IN MALARIAL HEMOGLOBINURIA.

STEGGALL, of Costa Rica, has reached the following conclusions upon this subject: (1) Quinine causes irritability of the kidneys and may cause hemoglobinuria. (2) Malarial attacks in chronic cases with malarial cachexia may cause hemoglobinuria. (3) In these cases quinine has lost much of its specific effect, and large doses must be exhibited. Should there be a periodicity, we must give the quinine before the time of attack. (4) The action of quinine must be assisted by such drugs as iron and arsenic, and, more important even than quinine, the liver must be acted on well, and the effect kept up. Dr. Steggall says he has never been able to cure an attack of hemoglobinuria without getting the liver active; the bilious vomiting in these cases sufficiently indicates the necessity of this.—Medical Record, Aug. 19, 1899.

BROMIDE OF CAMPHOR IN EPILEPSY.

LOUIS HASLÉ (Thèse de Paris, 1899) gives an account of careful clinical observations made with this drug in the treatment of epilepsies systematically or with constant success. It has given variable success in delirium tremens, genito-urinary troubles, particularly b phenomenas with painful erections (Bourneville), and in retention of urine from hyper trophy of the prostate and spermatorrhoea. Haslé, after carefully selecting a number of cases of epilepsy from the abundant material at Bicêtre, obtained the following very constant results: (1) As regards epilepsy proper (haut mal), the action of bromide of camphor was doubtful, and was less effectual than the mixed bromides of potassium and sodium and ammonium. (2) In attacks of petit mal, and in all cases of epileptic vertigo, however, its effect was incontestable; it at first diminished the frequency of the vertiginous attacks, and finally made them disappear.
altogether. The condition to be observed in prescribing was to begin with moderate doses, made gradually progressive and lasting for a sufficient time. Owing to its disagreeable odor it is best taken in capsules of 20 centigrammes, or dragées of 10 centigrammes, beginning with two capsules per diem, and augmenting by two capsules the second week, etc., till eight capsules per diem are taken, then as gradually diminishing the dose till two capsules per diem are reached and maintained for some time.—British Medical Journal, Aug. 5, 1899.

RECENT ADVANCES IN PRACTICAL MEDICINE.

In delivering the address in medicine before the British Medical Association Sir Douglas Powell, in speaking of serum therapeutics, said that as he was in no way competent to discuss the question of serum therapeutics from the bacteriological side, he would only glance at it from the side of results achieved in the form of additions made, and others we may hope to make, to our therapeutics. It is already an immense achievement if we have acquired the knowledge that every infection requires a separately prepared serum for its treatment. It explains many of our failures, and gives promise of adding to our successes. It has for some time been recognized that infective endocarditis has a manifold microbe pathology—streptococcus, staphylococcus, pneumococcus, gonococcus, are some of the organisms concerned. It is useless to employ an antistreptococcic serum for a pneumococcus infection, and even the two organisms, streptococcus and staphylococcus, which seem to work most cordially in couples, require a separate treatment. Thus is in part accounted for the very poor success as yet achieved by the serum treatment of this and of some other maladies more or less allied to it. From the clinical side one would judge there to be very frequently more than one poison in association. This is certainly the case in many diseases—for example, in the third and often in the first stage of enteric fever, in the suppurative stages of tuberculosis, in scarlatina, and perhaps in gonorrheal rheumatism. In pneumonia, again, it is remarkable that in every variety of the disease—the sthenic, the asthenic, the typhopneumonia, the septic pneumonia, and the influenzal catarrhal forms—the characteristic pneumococcus is invariably to be found, and this coccus may be the microorganism conspicuously present in those secondary lesions with which pneumonia is often complicated, and which are attributed to it, such as empyema, infective endocarditis, etc. Yet there are, Dr. Powell thinks, good reasons to doubt whether the pneumococcus organism alone, unassisted by some of its pyogenic confrères, is ever able to bring about these secondary lesions which are usually attributed to it. We must push our diagnosis further, then, to include a recognition of the precise organism or organisms which have obtained lodgment in any given case. Unfortunately in the earlier stages, at least of ulcerative endocarditis, bacteriological investigation is by no means always successful in identifying the organism, or indeed in recognizing any organism, for with well marked clinical features the specimen of blood examined may be sterile. We may yet for some time to come, therefore, as in complex cases of enteric fever, with which these cases are often confounded, have to rely upon the general clinical phenomena presented by the case and its history of attack in our attempt to identify the poison and in our endeavor to select the antidote.

Whilst the possibility of neutralizing by appropriate treatment the specific poison in certain diseases will relieve practitioners of some anxiety, it cannot fail on the other hand to add much to the tension of their labors by requiring an earlier diagnosis, and by the great care needed to avoid accidents in the use of delicate organic fluids, prone to contamination and decomposition. It is impossible that the treatment can be much developed in general use until abundant local centers are secured for the provision of materials of guaranteed purity.

It is curious and instructive to note that in the two diseases in which antitoxins are of most approved value, namely, diphtheria and tetanus, the bacillary cultivation is declared (Behring) to be limited to the seat of inoculation, the blood only being charged with their toxins. Whereas the mortality from diphtheria but a few years ago varied from twenty-five to fifty per cent, according to the severity of the epidemic, it has been reduced by the serum treatment from twenty-five to eight per cent, according to the severity of the case and the date of infection.

Unfortunately, we have not yet been supplied with any reliable antidote for the serum treatment of pneumonia. Dr. Powell was
good-naturedly twitted by some of his friends in their criticism of a book published eight years ago, because he did not speak well enough of the then recent observations of Dr. Klemperer on the serum treatment of pneumonia; but in a paper read before this Association in London five years later he could say no more, and to-day, although Pane’s antipneumococcic serum will protect a donkey or a rabbit from the evil consequences of a strong dose of pneumococcus infection, it has not as yet come into practical use in the human disease. He has recently tried it in two cases without result. This may be due to three causes: In the first place, it is difficult to use the serum early enough in the disease; secondly, the most severe cases in which alone at present one feels disposed to try the remedy are most generally complicated with other infection, so that the pneumococcus in the sputum does not signify the sole—perhaps not the most important—element of danger in the case; and thirdly, the doses employed by Dr. Pane have been very large, so large that one shrinks from introducing in such bulk an unknown or imperfectly accredited element into any case not already desperate. In the use of these very large doses Dr. Charles, of Rome, has suggested the introduction of the serum per rectum as a method which he has known to prove efficacious with other serums, the absorption being rapid and the serum being unchanged. As yet, however, the serum cannot be obtained in sufficient quantity for use in such large doses. In all probability the want of success, with casual exceptions, in the antitoxin treatment of erysipelas, puerperal fever, and allied affections, including infective endocarditis, may be similarly accounted for by the presence of more than one organic infection, thus requiring, as pointed out by Behring, Pfeiffer, and Kanthack, more than one antidote.—The Lancet, Aug. 5, 1899.

THE EFFECT OF BATHS, MASSAGE, AND EXERCISES ON THE BLOOD-PRESSURE.

The British Medical Journal of August 5, 1899, details some experiments of Edgecombe and Bain on this subject. The instrument used was Oliver’s hemodynamameter. The maximum and mean arterial pressures, and the venous pressure, were recorded; the maximum pressure, as taken by the instrument, being the amount of pressure in millimeters of mercury required to just prevent the passage of blood along the artery; the mean pressure being the reading taken when the indicator gives its maximum excursion; and the venous pressure being the amount of pressure requisite to just prevent the passage of blood along the vein. For arterial pressure the radial artery was employed; for venous pressure the veins of the forearm or back of the hand. The readings were taken in the same posture throughout each series of observations, with due precautions to eliminate the effects of gravity.

Eleven subjects were experimented on, their ages ranging from 20 to 60; they included marked examples of both low and high arterial pressure.

1. The following baths were used: (a) Cold, warm, and hot immersion baths of plain water, Turkish bath, Russian bath, sitz bath; (b) the needle bath, hot and cold, the alternating douche, the spinal douche; (c) the saline-sulphur baths of Harrogate, the artificial Nauheim baths, still and aerated.

2. Massage: (a) Dry massage, with and without massage of abdomen; (b) wet massage (Aix douche and Vichy douche).

3. Exercise: Resisted movements, dumbbell exercises, cycling.

The following conclusions were arrived at:

1. Cold immersion baths of plain water raise the arterial pressures, maximum and mean, and lower the venous pressure; after reaction the arterial pressure falls and the venous rises. The results may be attributed mainly to changes in peripheral resistance.

2. Percussion added to cold increases the rise in arterial pressure. In addition to increased peripheral resistance there is probably an increase in the output of the heart.

3. Hot immersion baths of plain water lower the arterial pressures, and both absolutely and relatively lower the venous pressure, to an extent roughly proportionate to the increase of temperature. The percentage fall in venous pressure is greater than the percentage fall in arterial pressure; and the changes are best explained as due in the first place to peripheral arteriolar dilatation, and in the second place to increased capacity of the vascular system resulting from that dilatation.

4. The Turkish baths lower the arterial and venous pressure to a greater extent than the preceding, though the fall in venous pressure is proportionately not so great as that in arterial pressure. The pulse-rate is greatly increased. Associated with peripheral vas-
cular dilatation there is probably a diminished output of the heart, which would explain the greater fall of arterial pressure.

5. Saline baths at warm temperatures lower the arterial pressure to a greater extent than plain water baths at the same temperatures; the venous pressure is raised relatively to the fall in arterial pressure. When the saline material is increased or when effervescence is added (Nauheim bath), a further lowering of arterial pressure takes place, while the venous pressure becomes absolutely raised.

6. Dry massage lowers arterial and raises venous pressure. When the abdomen is massaged a general rise in blood-pressure occurs. This is due to the dispersal of blood accumulated in the splanchnic area into the systemic circulation.

7. The Aix douche lowers arterial and raises venous pressure to a greater extent than dry massage. The Vichy douche raises arterial pressure. This is probably due to the fact that a needle spray is used and the patient is in the recumbent posture, and consequently abdominal massage is more efficiently performed.

8. The effect of exercise on the blood-pressure depends on the severity of the work performed.

After these general statements, Dr. Einhorn says a few words with regard to the special management of malignant disease in the different portions of the digestive tract.

Cancer of the esophagus and cardia does not for the present permit of any radical operation. As soon as the diagnosis is positive and the dysphagia is such that the patient is not able to partake of sufficient liquid and semiliquid food in order to maintain his weight, gastrostomy should be performed wherever feasible.

Cancer of the stomach and the entire intestinal tract should be operated (i.e., removed), if discovered early enough. Practically the outlook for a cure after a radical operation of some portion of the intestinal canal becomes less encouraging the farther away from the anus the tumor is situated. Malignant disease of the pylorus can often be recognized quite early through the isochromia which it usually produces. In these instances a laparotomy should be performed as soon as possible and the pylorus resected, with establishment of a new communication between stomach and duodenum if possible; if not, a gastroenterostomy alone should be made. The latter operation is in many cases of decided benefit, facilitating nutrition and rendering the pains less.

Cancer of the lesser curvature of the stomach or of the posterior wall is usually recognized quite late, rendering radical operations practically impossible. If the cardia and pylorus are not involved, there will be no need of any operation, and the usual palliative remedies should be administered. The same may be said also of cancer of other portions of the stomach not involving either cardia or pylorus, in which a radical operation does not appear possible.

Cancer of the rectum can be recognized at an early stage, and resection of the neoplasm is here accompanied by brilliant results. If the tumor is located farther up in the large bowel or the small intestine the results of an operation are not so promising, for here the recognition of the growth is possible only at an advanced period, and by that time often adhesions with other organs and cancerous infection of the glands have already taken place.

Excision of the tumor and resection of the intestine in the neighborhood of the neoplasm, with an end-to-end anastomosis, should be practiced whenever feasible. In case, however, total resection is impossible, an enteroenterostomy or enterocolostomy,
or, if the cancer is situated in the rectum, a colostomy (artificial anus) will be of benefit. These operations are palliative in nature and prolong life, at the same time making it more comfortable. They are intended to allay the symptoms of obstruction and to carry the fecal matter over a new route, not passing through, and thus not irritating, the cancerous area. In some instances of inoperable cancer of the rectum curettage, followed by the application of the thermocautery, may be of benefit for a short time.

MODERN THERAPY OF THE TYPANIC CAVITY.

Under this title Goldstein tells us in the New York Medical Journal of July 29, 1899, that in a brief paper recently published by him he attempted to compare the two systems of treatment which have in recent years been given every practical test—one, the so-called "dry treatment;" the other, irrigation and syringing with various antisepic solutions. In summing up the advantages and disadvantages which either of these methods might afford, he has considered the pathological status of the affected area, the character of the discharge, and the size of the perforation, as factors.

From a close comparison of these two methods he believes that frequent use of the syringe and lavage of the auditory canal are distinctly contraindicated in supplicative cases where large perforations of the membrana tympani exist, and where a free entrance of the fluid into the tympanic cavity is so easily effected. In the first place the mucous membrane of the tympanic cavity, bathed in purulent secretions, affords an excellent supply of infectious material, which the force of the current from the syringe or douche may wash into the remote and healthy areas of this cavity and thus mechanically produce an infection of the attic or antrum where none had previously existed. He thinks he can substantiate the assumption that many of the cases requiring mastoid interference or ossiculectomy have been unconsciously produced by the too liberal use of the syringe in the cleansing of the tympanic cavity.

Otolological literature contains frequent references and admonitions as to the indiscriminate use of the nasal douche, especially when handled by the patient himself, and points to a subsequent infection of the tympanic cavity as the result of this procedure. If this is so frequently possible by the carrying through of the entire tract of the Eustachian tube, how much more readily can a similar result ensue when the syringe is brought directly in contact with the tympanic cavity through a large perforation of the membrana tympani.

The second factor contraindicating the use of aqueous fluids in these conditions is the pathological status of the tympanic cavity itself. The mucous membrane of the tympanic cavity during a supplicative otitis is constantly bathed by purulent secretions, resulting in a sodden, boggy surface, and this is accentuated by the addition of aqueous fluids. It is this very stimulation and irritation of the mucous membrane by the fluids with which it is brought into contact that causes granulation and polypus formation. It should be our object to extract fluid from this area and not to add to the already existing serous or purulent infiltration.

Where the discharge is viscid, tenacious, and copious, the application of the syringe with a gentle current of a mild, warm antiseptic fluid may be advocated to clear the auditory canal to the surface of the membrana tympani. Beyond this point, however, it is Dr. Goldstein's opinion that the syringe should not be used in suppurring conditions of the tympanic cavity.

Clearing the auditory canal of these copious discharges may be just as readily accomplished by the use of strong solutions of peroxide of hydrogen, such as hydrozone or the full-strength H₂O₂. This obviates the necessity of the syringe and the considerable pressure of the current of the fluid which is often necessary to dislodge these ropy purulent shreds.

Dr. Goldstein is also opposed to the use of the middle-ear syringe in any affections of the tympanum other than in mild cholesteatoma. Here we deal with a moderately dry cavity, and an alkaline antiseptic solution used with a middle-ear syringe is frequently effective in detaching these epithelial masses.

The method in surgery which has found general favor of late is the "dry dressing." Its advocates and enthusiasts claim for it a more rapid healing, a more natural covering, less irritation of the injured surface, and less danger from infection of the surrounding areas. The "wet treatment" always produces an infiltrated surface, and as this in the ear is generally applied to the mucous membrane, it unintentionally aggravates the condition of "bogginess" which is our purpose to subdue.
For clearing the auditory canal of pus or mucopurulent discharges, Goldstein has found a small tuft of sterilized cotton wound about the end of a probe or cotton carrier, frequently renewed, and gently applied as a mop, a more effective cleansing agent than a large current of antiseptic fluid.

If but a small perforation exists and the cotton tuft cannot find its way through this perforation into the tympanic cavity, there is always a possibility of retention of the putrid matter and a tendency to prolonged suppuration. In suppurative otitis media of a chronic character, where no pain or discomfort exists, he employs the Eustachian catheter in connection with a nebulizing or vaporizing apparatus, thus accomplishing the threefold result of inflating the middle-ear cavity, of clearing the tympanum of pus and forcing it by a medicated compressed-air current through the perforation, and of medicating the middle-ear cavity more effectually and with less unfavorable possibilities than by the use of an aqueous fluid. His nebulized fluid consists of iodine three grains, carbolic acid four grains, and benzoinol or albolene one ounce. This he uses in conjunction with a hand nebulizer, the supply tube of which is fitted with a special tip, which in turn is snugly adjusted to the proximal end of the Eustachian catheter. In this way his medicated vapor is insured a thorough penetration of the tympanic cavity, and the inflation may be continued ad libitum. The simplest index for determining the volume of vapor which reaches the middle-ear cavity in this manner is to watch the vapor as it passes out of the auditory canal. He has frequently succeeded by this steady inflation, continued for five minutes at a time, in forcing the residue of the purulent matter through small perforations of the membrana tympani in a single sitting, and long-standing cases of suppurative otitis media have yielded to this treatment where all other methods have failed.

An antiseptic powder lightly insufflated completes this treatment. Boric acid, which has for so many years been the sheet-anchor of otologists in the treatment of suppurative conditions of the middle ear, is hardly of sufficient antiseptic strength to meet all the demands of modern surgery; iodoform is objectionable, first, because its germicidal action is often questionable, and secondly, because of its disagreeable odor. Dr. Goldstein's preference has been for nosophen, as an ideal powder dressing in the ear, being more potent than boric acid in its antiseptic qualities, odorless, and less irritating than iodoform and with no tendency to clog. Where the discharge is profuse he adds to this treatment a gauze packing, selecting narrow strips of plain sterilized gauze in preference to that of iodoform, as previously advocated.

Goldstein also takes this occasion to state that he has now in preparation a paper and report of experimental work on the antiseptic value of certain nebulized fluids on the various microorganisms found in the middle-ear cavity, and he offers the preliminary statement that vaporized oily antiseptics when brought into contact with pure cultures of streptococci and staphylococci afford surprising germicidal results.

It is his further opinion that in the evolution of medications employed in the treatment of the mucous membrane of the upper respiratory tract and of the ear, oil sprays in their various combinations will soon gain the upper hand.

For some time past he has been using medicated liquid petroleum in the treatment of chronic non-suppurative middle-ear catarrh of the hypertrophic form, and has even found this therapy of advantage in mild sclerotic otitis media.

The applications to the tympanic cavity are made as follows: A short hard-rubber Eustachian catheter is introduced in the usual manner and snugly fitted into the nasopharyngeal orifice of the Eustachian tube. Goldstein emphasizes the necessity of this snug fitting to avoid any leakage at the tip of the catheter when the fluid is forced into the tympanic cavity. For this purpose he uses a glass barrel syringe, two inches in length and half an inch in diameter, supplied with a cone-shaped tip by which an air-tight joint is made with the end of the catheter. The syringe is loaded with the above mentioned solution of iodine, carbolic acid, and benzoinol or liquid albolene. When the catheter and syringe are properly adjusted the patient's head is tilted well backward and inclined toward the ear to be medicated. This position has been found the most favorable one for the introduction of the solution. The piston is now pressed home slowly, and in the majority of cases, after six or eight drops have been delivered, the patient will state that he feels an unusual fulness in the ear. The syringe is then detached and the cone-
applied; a few short taps, and then a steady pressure continued for eight or ten seconds is given. This insures the penetration of the tympanic cavity by the fluid. He has convinced himself on numerous occasions of the penetrability of this fluid by applying it not only in chronic catarrhal conditions of the middle ear where the membrana tympani was intact, but also in the treatment of middle-ear cavities, suppurrative or non-suppurative, where perforations of the drum membrane existed; where such perforations are present this dark-colored oily fluid may be found on examination exuding into the auditory canal.

The urine from two normal ewes after delivery contained no sugar.

Paul Bert believes that the milk - sugar is formed, not in the mammary gland, but in other parts of the body, probably in the liver.

In answering the second question Routh asserts that full-term gestation and lactation proceed normally after complete double ovariotomy. This is abundantly proved, for numerous instances are recorded, but the following will suffice:

In the case recorded by Dr. Lapthorn Smith, full-term delivery occurred 267 days after operation, and lactation was normal. Two cases of Mr. W. A. Meredith were also reported to the Obstetrical Society of London, where gestation lasted the full period—in one case 301 days from the last day of the last period, and the other was slightly over the nine calendar months. They both nursed their children without any evidence of abnormality. The answer to these two questions therefore seems to be, first, that the removal of both mammary glands does not interfere with ovulation, and secondly, that the removal of both ovaries does not interfere with lactation.

A further question may now be asked: Is there any evidence pointing to the mammary glands being affected by states of the pelvis?

In normal physiological conditions it is fairly certain that functional activity of the mammary glands is usually manifested during temporary abeyance of ovarian function, as in pregnancy and lactation; but that mammary-gland activity may continue while the function of ovulation is also proceeding is shown by cases of superfetation, tubal gestation coexisting with normal gestation of a different date, pregnancies of different dates in the two horns of a double uterus, as well as by the fact that ovulation not infrequently recommences during lactation, so that conception may take place without menstruation having recurred; and Gillet, of Toulouse, states that milk secreted during menstruation is more dense and more rich in fat and less rich in sugar.

In pathological states of the pelvis there is no doubt that the mammary glands are greatly affected by pelvic congestion, and evidence tends to show that functional activity, or in other cases chronic hypertrophy of the mammary glands, may occur more as a result of uterine than of ovarian conditions.

Several curious cases of enormous hypertrophy of the mammae have been recorded.

ON THE INTERACTION BETWEEN THE OVARIES AND THE MAMMARY GLANDS.

Amand Routh contributes a paper on this subject, to which we have referred editorially, to the British Medical Journal of September 30, 1899. He points out that in addition to the internal secretion of the ovary and of the mammary gland, each of these organs has a special function—ovulation and lactation respectively.

By studying these two functions separately and in combination, one may perhaps be in a position to ascertain whether there is any interaction between the ovaries and the mammary glands.

The following questions should be easily answered:

1. Can ovulation occur in the absence of the mammary glands?
2. Can lactation take place in the absence of the ovaries?

In reply to the first question Routh says he does not know of any cases where both breasts have been removed in a woman during active sexual life, but it is probable there are such cases recorded, and it is probable, too, that both menstruation and ovulation would be unaffected.

Paul Bert’s experiment on two ewes proves that ovulation and conception may take place, in ewes at all events, when the breasts are removed, and it has a special bearing on the secretion of milk also.

Paul Bert removed the mammary glands from two ewes, and after the wounds were healed put them to a ram, and they became pregnant, proving that the function of ovulation was being duly performed. During pregnancy the urine was free from sugar, but after delivery it contained sugar for several days, and then it gradually disappeared.
associated with uterine disease. Dr. William Aitken describes one such case—Case II in his paper—where the vaginal portion of the cervix uteri was elongated and catarrhal. A somewhat similar case was described by Routh's father, Dr. C. H. F. Routh, at the International Medical Congress at Brussels in 1892, where bilateral hypertrophy of the mammae occurred in a young woman whose infravaginal cervix was found to be six inches in length. The cervix was amputated, and the mammary hypertrophy gradually but completely disappeared. M. Bouyer, of Saintes, describes a case of enormous sudden hypertrophy of both mammae in a girl of fifteen, following arrest of the catamenia. She was not pregnant. Her right breast weighed 20½ pounds, the left 30½ pounds, whilst the patient herself weighed 101 pounds. Another case shown to the Académie des Sciences, Montpellier, in 1878, had also enormous hypertrophy of both mammae following a cold bath at the onset of her catamenia when 15½ years of age.

The following statement by Dr. W. S. A. Griffith has been recently published and bears on the same point: "There is a direct connection between septic conditions of the uterus and a form of mastitis, a connection which, when first pointed out to me, I was slow to admit, but of the fact I have now no doubt; and in every case of pyrexia with a blush on the breasts, I would urge the importance of examining the interior of the uterus, where frequently will be found some putrid clot or remains of placenta. The removal of this, followed by thorough irrigation of the uterus with an efficient antiseptic, leads to a rapid disappearance of the so-called ‘breast symptoms.’"

Assuming, then, that there is an interaction between the uterus and the mammary gland, how is this influence initiated, and how is it conveyed to the mammary gland? Routh has shown how the uterine state influences the mammary glands, and the following cases tend to show that the influence is not conveyed through the nervous system, but through the circulation:

A case of paraplegia in pregnancy reported by Dr. Routh in Obstetrical Society Transactions, vol. xxxix, 1899, p. 191, proves that lactation was not induced in that case by the conveyance of nervous impressions from the pelvis to the mammary glands along the spinal cord. The woman, when six months pregnant, fractured her spinal column, and was paraplegic below the level of the sixth dorsal vertebra. She was confined about full term (26½ days) without assistance, but with no sensation of pain. Involution was normal, and so also was lactation. She subsequently died, and investigations by Dr. F. W. Mott, Dr. Pembrey, and Dr. William Hunter, showed that the spine had been broken completely across through the intervertebral disk between the fourth and fifth dorsal, the two broken ends overlapping at an angle of 135 degrees. At the seat of the fracture the microscopical sections could not have been recognized as those of a spinal cord, both gray and white matter being completely disorganized and the degeneration complete.

A somewhat similar case is related by Dr. Mercier, where, though paraplegia was present due to cancer involving the dorsal region of the spinal cord, both gestation and lactation were absolutely normal.

These cases tend to show that there is a chemical or biochemical influence present between the pelvic organs and the mammary glands, and that this must be conveyed through the blood, so that it is possible that the internal secretion of the uterus may be the origin of this influence. Moreover, Michael Foster states that milk is secreted when the mamma is deprived of all connection with both the spinal and sympathetic system, though the nipples are not then capable of becoming erect.

It is known that the mammary glands are called into functional activity, milk often being secreted when an ovum dies in utero, even before it is expelled.

These facts tend to show that lactation is due to some chemical change in the blood which, in a normal gestation, is produced within a short time after a gravid uterus ceases to contain a living fetus, whether it be at once expelled with its placenta and membranes, or remain for a time in utero as in missed abortion or missed labor.

There is more or less sudden cessation of nutritive requirements previously needed by the fetus, and probably a correspondingly sudden absorption into the maternal circulation of waste products involved in the separation of the placenta and in the process of involution. The biochemical change is almost certainly in the uterus and not in the ovaries, and is practically an internal secretion. There seems to be no evidence in favor of any essential interaction between the mammary glands and the ovaries.
SOME POINTS CONNECTED WITH SLEEP, SLEEPLESSNESS, AND HYPNOTICS.

BRADBURY, of Cambridge, England, in this year’s Croonian lectures devoted his attention to a consideration of hypnotics, and in his closing lecture he dismisses the general theory of his subject and passes on to the special therapeutics of insomnia, which may be divided into non-medical and medicinal measures. The first of these, as it is more or less common to the treatment of all insomnias, will be dealt with first. In all cases, where practicable, the bedroom ought to be in a quiet part of the house, well ventilated, and of moderate temperature. Light should be easily excluded and the apartment scantily furnished. The bed should vary according to the custom of the individual—for young and middle-aged adults a firm mattress is the best, but for the old a softer bedding may be necessary. The covering should be light and warm, but in the use of pillows no general recommendation can be made. Some people sleep better with the head raised, others with the head on a level with the body. In heart disease it will be found necessary to raise the head, but as a rule this arrangement may be left to the choice of the individual. For broad-shouldered people, Whitla recommends the wedge-shaped pillow used by the Germans. Some invalids find much refreshment from the use of two beds—one for the day and the other for the night. In individual cases various means must be resorted to for the purpose of inducing sleep, and often simple ones suffice. Thus some people read themselves to sleep, some people count, other people, like Southey, think of some monotonous discourse. One of Dr. Bradbury’s patients used to hang his feet out of bed for some time and then put them in again. Walking about naked or taking a cold or tepid bath is often useful. Massage, especially of the abdomen, the thighs, and the legs, as in Dr. Eccles’s method of treating insomnia, is sometimes advancegous. This method is believed to produce temporary anemia of the brain by causing a determination of blood to the manipulated parts, and it may be further aided by a hot compress to the abdomen. In the case of cold feet rubbing them vigorously, or the use of a hot bottle or a foot-bath with mustard in it, is beneficial; or, again, a hot sitz bath may be used. Attention should also be given to the condition of the stomach. As a rule a light supper is the best, and for many, and especially those who awake in the middle of the night, a little hot milk or meat juice containing a small amount of alcohol is helpful. The evacuations should also be attended to and the bladder especially be relieved.

Sleeplessness from overwork, and especially literary work, requires mental rest and change of air and scene. Temporary exposure to the cool air of the bedroom, or the wet pack or a bath, is often of use, and so is a glass of whiskey and water at bedtime, especially in those unaccustomed to the use of alcohol; but if the insomnia continue it is necessary to give a mild hypnotic, such as 20 grains of sulphonial or 30 or 40 grains of bromide of potassium, to break the habit of sleeplessness. Capsules containing 30 minims of turpentine given at bedtime are sometimes beneficial in the insomnia of overwork and worry. The drug acts as a stimulant and derivative and is stated to be most successful in plethoric cases. No beverages containing caffeine should be taken after breakfast.

In nervous and hysterical women, and especially in women at the menopause, the bromides are very useful. Dr. Bradbury has long been in the habit of giving a mixture of bromide—either of potassium, sodium, or ammonium—tincture ofumbelliferae, and tincture of hops, in camphor water, at the climacteric; and it has helped to remove the insomnia as well as the mental depression and flushing heats so common at this period.

The sleeplessness of the insane requires careful management. In the early stages of acute mania the bromides, chloral, hyoscine, hydrobromate, and other sedatives are useful, but a hot bath at a temperature of 104° F. and cold water simultaneously poured upon the head are most efficacious in inducing sleep. In melancholia, where arterial tension is usually high, paraldehyde in doses of from 40 minims to 90 minims or even more is a valuable hypnotic, and so is morphine, but a one-grain dose of erythrol tetranitrate by reducing arterial tension will frequently act better than anything else. In mild cases of delirium tremens sleep usually comes on after a time whatever treatment be adopted; in the more severe cases chloral and bromides, alone or in combination, are beneficial. Paraldehyde is recommended by some physicians. Opiates may be given, but in most cases hyoscine is probably a more efficient remedy. Among the medical officers of the American army 20 grains of powdered capsi-
cum in the form of a bolus is the favorite hypnotic for this complaint. Dr. Bradbury says he has had no practical experience of this prescription, and therefore cannot express any opinion of its value as a mode of treatment. Cerebral depressants should be given as little as possible, and the treatment should be confined chiefly to feeding and tonic measures.

In pneumonia sleep usually comes at the crisis, but where this has not occurred he has occasionally seen a hypnotic; such as chloralamide or paraldehyde, turn the scales in favor of the patient. In pleurisy and most other serious inflammations, from five to ten grains of Dover’s powder usually conduce to sleep mainly by relieving the pain. A hypodermic injection of morphine may be given with the same object in view. In bronchitis chloral and chloralamide are safe hypnotics, and as a rule opiates are to be avoided, as these depress the respiratory center. The sleeplessness of asthma is relieved by remedies which cut short an attack, such as chloral hydrate, the fumes of asthmatic powders, the hypodermic injection of morphine, or in some cases from a five-grain to a ten-grain dose of citrate of caffeine. Bromides are also useful, and so is paraldehyde, which both relieves the asthma and causes sleep. A change of locality even to another part of the same town often succeeds. In one case the removal of a student from Downing College, Cambridge, to a house across the street brought relief, and in another of Dr. Bradbury’s pupils the change from Caius College to a house in another part of the town brought to an end a most troublesome attack of asthma with its attendant sleeplessness.

The insomnia of heart disease is benefited by digitalis, strophanthus, strychnine, and other cardiac tonics, but in some cases it is necessary to resort to morphine either by the mouth, or, still better, hypodermically, as first suggested by Professor Allbutt. Paraldehyde and chloralamide are in Dr. Bradbury’s experience most useful. Ice to the head is recommended by Morison where the vital forces are not too low or the temperature subnormal. It often produces sleep rapidly, with a more regular cardiac action. Heat may possibly answer in other cases presenting a subnormal temperature. In chronic Bright’s disease insomnia is occasionally very troublesome. Eliminants such as aperients should be tried, and if they do not succeed chloral hydrate may be given.

The drug is safer in kidney than in heart disease, the reduction of blood-pressure being usually beneficial rather than otherwise. Morphine and hyoscine hydrobromate subcutaneously injected have been recommended in obstinate cases, but their employment requires great caution. Erythrol tetrani trate, by reducing arterial tension, often acts as a charm even when sedatives have failed; and in one of Dr. Bradbury’s patients thorough rubbing of the skin by means of a flesh-brush induced sleep and very materially relieved the restlessness of the disease. When pain is the causal factor of insomnia morphine is usually the best remedy, and this should be pushed until relief is obtained. In cases of neuralgia, locomotor ataxia, and so forth, some of the synthetic analgesics—phenazone or phenacetine—are of value. These drugs, as has been previously stated, act also as hypnotics in cases where there is no pain. Calcium chloride is a valuable remedy in the insomnia due to pruritus.

HEADACHES OF GASTROINTESTINAL DISORDERS.

The treatment of headaches of gastrointes tinal origin is palliative and curative, according to Frank Billings, who writes on this theme in the Journal of the American Medical Association of September 23, 1899. The palliative measures consist in removing the source of the poison by emptying the stomach, by emesis or lavage; moving the bowels by cathartics or by colonic flushing; promoting excretion of the poison from the blood by diluent drinks to aid skin activity and diuresis; and relieving the pain by small doses of the bromides combined with caffeine, or by the cautious use of phenacetine or some of the other petroleum derivatives, or, in very severe cases, by a small dose of morphine hypodermically. In incurable organic disease of the stomach palliation will be the limit of treatment.

Curative treatment will consist of the application of the laws of hygiene, modified to suit the individual case; a selected diet for each individual; the free use of pure water as a diluent drink; recreation in the form of physical exercise or physical rest, commensurate with the mental activity or physical tire of the individual; the correction of irregular habits of sleep, of time of taking food, and of exercise; the withdrawal of tobacco, tea, coffee, and alcoholic drinks, which is usually necessary, and especially in
the patients who suffer from the neuroses. Lavage the stomach when necessary and overcome the constipation by hygienic measures, if possible, without drugs. In the conditions of malnutrition and anaemia, give restorative tonics and an abundant simple diet. In short, a sensible hygienic life will not only prevent the headache, but will usually remove the gastrointestinal disease or cause.

THE LOCAL TREATMENT OF PUERPERAL INFECTION, WITH ANALYSIS OF FORTY-EIGHT CASES.

In the Medical Chronicle for September, 1899, Lea lays down certain principles of local treatment which are briefly as follows:

A rise of temperature of over 100.4° during the puerperium should lead to careful investigation as to its cause.

A rise of temperature may be due to constipation or gastric irritation, to mental emotion, tension of milk in the breasts, or to some intercurrent disorder. If these can be excluded it is probable that the pyrexia is the result of some form of infection.

If the temperature rises to 101.4° or more, and this is not obviously accounted for by any of the above mentioned causes, a careful examination of the genital tract is made. If the perineum and vagina are uninjured, or even if there is a laceration which appears to be healthy, a uterine douche is given. For this purpose a double-channel glass or metal catheter, after the model suggested by Budin, is used. The cervix should be fixed by a vulsella, and it is advisable to introduce a duck-bill speculum, and previously cleanse the vagina and cervix thoroughly by a douche. The solution used for the intrauterine douche should be a mild antiseptic, such as carbolic acid (1:40), tinctura iodi (a teaspoonful to the pint), or perchloride of mercury (1:4000), followed by a douche of saline solution or plain warm water.

If after twenty-four hours there is not a marked improvement in the pyrexia and general condition, or if the temperature continues to rise, the uterine cavity is explored by the sterilized finger. This step is taken earlier if there is evidence of retained products in utero. In every case the finger will detect shreds of decidua, and the placental site is felt to be projecting into the body of the uterus and has a roughened surface.

If any retained products (clots, decidual débris, membranes, or placenta) are found, these should be removed by the finger, and it is often necessary to use a blunt flushing curette to insure complete removal. After this procedure a douche is again given, and a gauze drain introduced into the uterus.

If, however, the symptoms at the time of exploration are severe, as shown by high fever, quick pulse, and abdominal tenderness, the uterine cavity is thoroughly curetted, with the object of removing the infected decidua. After this, the cavity is thoroughly swabbed with cotton-wool soaked in perchloride solution (1:2000), and a strong antiseptic applied to the interior of the uterus. In some cases tincture of iodine has been used, or carbolic acid (fifty-per-cent). Latterly a solution of creosote and alcohol, fifty-per-cent, as recommended by Budin, has been adopted.

The uterus is now lightly packed with ipidoform or aseptic ganze, which is removed at the end of twenty-four hours.

Ergot should be given as recommended by Bumm. It stimulates the uterine muscle to contract, thus mechanically compressing the blood-vessels and lymphatics, and diminishing the absorption of poisonous products. It is best given hypodermically (ergotin gr. ij every four hours).

The use of an anesthetic is not necessary in every case. Much depends on the type of patient. If there is any laceration of the soft parts, exploration of the uterus may cause great pain. In many of these cases chloroform was given. Pinard strongly advises against the use of anesthesia, and never adopts it in his practice. He recommends that no speculum be introduced; the cervix is seized by a vulsella, guided to it by the finger, and the uterus drawn down towards the vulva. If care be taken that the vulsella forceps do not press upon the soft parts anteriorly, the uterus can be explored and curetted without causing any pain.

The value of vaginal douches in the treatment of puerperal infection has been much overestimated. They have little therapeutic effect, and may be actually harmful. The vagina is well protected by stratified epithelium, and is never the source of infection or absorption unless a laceration is present. The douche prevents accumulation of the lochia in the vagina, and may have a slight value if the cervix is infected. It is possible also that it may reflexly stimulate the uterine muscle and thus promote the escape of discharges. The fluid, however, does not reach the interior of the uterus, and hence can have little effect in the great majority of cases, in which intra-uterine absorption is the most
important factor. Great care is also necessary to avoid the introduction of infective material from the perineum or vulva, especially if lacerations or raw surfaces are present, since the tube may readily carry organisms into the vagina or lower segment of the uterus.

The use of the uterine douche is by no means free from danger, and some have proposed that it should be abandoned altogether. As a mode of treatment it may cause abrasion of the uterine mucosa unless the direction of the canal be known beforehand. The cervix should be fixed by a vulsellum, and the tube passed very gently and slowly. In some cases alarming symptoms follow its use, such as collapse and shock, sudden rise of temperature with a rigor, or severe abdominal pain. To avoid any such complication, the fluid used should be a very mild antiseptic; it should be injected slowly without any pressure, and the fundus uteri should be controlled by the hand pressing above the pubes. In some cases the Fallopian tubes are very patent after delivery, and fluid has sometimes passed into the peritoneal cavity during the administration of a douche. In rare instances also fluid has entered one of the venous sinuses, or air embolism has been caused. These accidents are all very rare, and can be avoided if great care is used.

Continuous uterine irrigation has been strongly recommended by Pinard and others. Dr. Lea, however, has no experience of this mode of treatment.

The dangers of the curette are: (1) Perforation of the uterus. This has happened many times, and the walls of the puerperal uterus are sometimes very soft and thin, so much so that a curette may very easily be passed through into the peritoneal cavity, without giving any unusual sense of resistance. To avoid this accident a large curette should be used. It must be introduced with very great care, and the length of the uterine cavity measured before commencing to use it. A hand should also be placed on the abdominal wall to support the fundus uteri, and afford counter-pressure whilst the curette is manipulated in the cavity. (2) Hemorrhage. Bleeding is sometimes very free during curetting. This specially occurs if chloroform is given. It is, however, always checked by gauze packing of the uterus. (3) Air embolism. Pinard had one death from this cause, in a woman whom he curetted on the second day after delivery. This was no doubt due to detachment of a thrombus from one of the larger sinuses, allowing air to enter the circulation. He therefore advises that curetting should never be done before the third day. After this day there is little risk of this accident. (4) The curette has been held by some to be dangerous, since by its use raw surfaces are made in the cavity of the uterus, which may therefore facilitate the entrance of organisms and the spread of infection. If, however, a strong antiseptic be applied after the operation, this danger is to a great extent avoided.

The after-history of cases cured for puerperal infection is a very important subject. Is the recovery complete, or do many of the cases develop chronic metritis or pelvic peritonitis with disease of the appendages?

HYPODERMIC FEEDING WITH YOLK OF EGG IN ANEMIC CHILDREN.

MUGGIA, of Turin (Revue Mensuelle des Maladies de l'Enfance, May, 1899), has for some time treated children suffering from anemia and athrepsia by the hypodermic injection of a preparation of yolk of egg. Freshly-laid hen's eggs are taken and carefully washed before opening. The yolks are received into a sterile glass vessel, and are weighed and then mixed with a third of their weight of physiological salt solution. The mixture is then thoroughly stirred up with a glass rod, and filtered through aseptic absorbent gauze. The liquid thus obtained is of a bright yellow color and of homogeneous consistency, and can be used for hypodermic injection. It is well to begin with an injection of about one cubic centimeter made into the buttocks or the lumbar region, and provided asepsis is strictly observed throughout there is no local or general inflammatory reaction. The region of injection should be slightly massaged. The quantity of hypodermic injection is gradually increased till a limit of ten cubic centimeters per injection is reached. The duration of treatment varies according to each case, but in any case not less than one hundred cubic centimeters (twenty injections of at least five cubic centimeters per dose) should be administered. According to Muggia's observations it appears that both the body weight of the children and the percentage of hemoglobin in the blood increase in the case of athreptic infants. The number of red corpuscles also rises, and this occurs much more readily than if lecithin were administered in the same way.—British Medical Journal, Sept. 30, 1899.
DISINFECTION OF THE HANDS.

Sarway (Centralblatt für Gynäkologie, No. 41, 1899) conducted a series of investigations to determine how thoroughly the skin of the surgeon’s hands can be disinfected without the employment of antiseptics other than alcohol. He notes first that cultures can always be obtained from hands which have not been carefully prepared, and the number of germs which can be grown is increased by moistening such hands with sterile water. Moreover, the number is increased by five minutes’ vigorous washing with sterile water, sterile soap, and a sterile brush. If, however, after this vigorous washing the hands are again washed for five minutes in ninety-six-per-cent alcohol with sterile brush, and sterile cloths, the number of germs is slightly lessened. A ten-minute washing of the hands in hot water, 42° C., also diminishes the number of germs.

THE USE OF ANTI-STREPTOCOCCIC SERUM.

The Medical Press and Circular of September 27, 1899, has in it a paper by Bond upon this much-debated and interesting plan of treatment. He asserts that the success of the treatment in his cases was very marked, especially in two cases in which the disease was very extensive, and the constitutional symptoms severe. Within a few hours of the administration of the first dose the temperature was considerably reduced, and the patients expressed themselves as feeling much better, and three or four doses were sufficient to overcome the disease. The injections did not cause any cutaneous symptoms, such as are sometimes seen after the administration of the antiphthiseric serum, with the exception of some slight tenderness at the point of inoculation, which tenderness passed off without treatment in the course of a few hours. The site chosen for the injection was the subcutaneous tissue of the anterior abdominal wall, in the flaccid region.

The serum has also been used in other supplicative and pyemic processes, with varying success; in some cases no benefit whatever has been obtained from its administration. But in these cases it is necessary to remember that the antistreptococcic serum is only claimed to be of value in cases of streptococcus infection, and that it will obviously be of no service in diseases due to the presence of other organisms. A case in point occurred at his hospital a few weeks ago. A woman was admitted suffering from ulcerative endo-carditis following parturition. On admission her blood was examined bacteriologically and found to be sterile. Antistreptococcic serum was administered every day for a fortnight, but with no signs of improvement. Subsequently her blood was examined a second time, and the presence of staphylococci was demonstrated. No streptococci were found. In this case the antistreptococcic serum could not be expected to produce any benefit, seeing that the disease was due to other organisms. It is therefore advisable, before pronouncing this method of treatment to be a failure, to make sure that the disease for which it is used is due to the presence of streptococci; but it is not necessary to wait for the result of the bacteriological examination before commencing the treatment, as by so doing the disease is allowed to progress, and the chance of saving the patient’s life may be lost, whereas, even if the injection do no good, it does not appear to produce any ill effects.

OBSERVATIONS ON TONSILECTOMY.

The Journal of the American Medical Association of September 23, 1899, contains an article by Coulter, in which he concludes his review of the subject by the question: What, then, are the general results of tonsillectomy, as compared with those obtained by the usual operation of tonsillotomy, as is ordinarily done by the general practitioner or most specialists as well?

1. It gives a cosmetically perfect throat. It gives a throat practically precluding the possibility of a return of the tonsillitis. It gives a throat in which there can be no absorption of the toxins or bacilli into the lymph channels at that point; at the same time it certainly offers to the patient a better chance for recovery should he subsequently be subject to an attack of any disease affecting the throat, such as the exanthemata, diphtheria, or quinsy.

2. It liberates and allows a perfect action of the pillars and soft palate, the same result holding whether the pillars were adherent from inflammatory action or bound together by a cicatricial stump the result of a former tonsillotomy.

3. It removes a mechanical obstruction to the sound waves. This, in the case of those professional people who are compelled to use the voice in singing or speaking, is a matter of no little importance.

4. The operation, thoroughly and properly done, is more likely to be effectual in reliev-
ing a reflex disturbance when such neurosis is due to a pathologic tonsil than is the more simple operation of tonsillectomy.

5. If thoroughly and properly done, and the case receives the proper subsequent care and treatment, it will leave a perfectly smooth surface in place of the tonsil, which result cannot as certainly be attained by a tonsillectomy, and with ignipuncture it is a practical impossibility. With singers this becomes an important matter.

6. Pillars which were for many reasons previously hypertrophied will ordinarily, after this operation, promptly retract to a normal contour and size.

7. It is in some cases a practical operation where another would be almost or quite impossible—for instance, in those tonsils which on the surface are so soft and degenerated that a firm hold on them cannot be obtained by any instrument; to obtain satisfactory results these must be dissected out entirely.

INFLUENCE OF MATERNAL INEBRIETY ON THE OFFSPRING.

Dr. W. C. Sullivan, of H. M. Convict Prison, Parkhurst, publishes in the Journal of Mental Science (July, 1899) a number of observations of the rôle of maternal alcoholism as an agent in race degeneracy. It has been observed by most authorities that those classes of individuals who exhibit marked incapacity or inability to adapt themselves to normal social conditions—e.g., many feeble-minded and imbecile subjects and a considerable portion of habitual criminals and prostitutes—are largely recruited from the offspring of the alcoholic. Thus, of a series of 1000 idiots examined by him Bourneville noted alcoholic parentage in sixty-two per cent, Marro observed an alcoholic parentage in forty-six per cent of criminals, while forty-five per cent of inmates in the Swiss prisons for juvenile offenders showed a similar past; and Madame Tarnowsky found that eighty-two per cent of Russian prostitutes were the offspring of alcoholic parents. To observations of this kind it has been objected that as parental drunkenness is an easily traceable antecedent it would tend to figure disproportionately among the causes assigned in such inquiries, and that in many cases it may get the credit of bringing about in the stock a degenerative taint which really existed prior to it, and of which it was, in fact, merely a symptom.

To avoid this possible source of fallacy, it seemed desirable to adopt at the outset an opposite standpoint and to take as an end of the investigation, not alcoholism in the ancestry of the degenerate, but degeneracy in the descendants of the alcoholic. For this purpose a series of cases of chronic drunkard women who have borne children were selected from the female population of Liverpool prison, among whom habitual inebriety had been very prevalent. All cases exhibiting a phtisical or syphilitic history were excluded from the inquiry, as well as cases which were the subject of marked neurotic taint as manifested by a specially early and violent cerebral reaction to alcohol. This process of selection avoids the more obvious source of fallacy in such inquiries, though certain qualifications are still to be considered. These drunkards who find their way to prison belong, for the most part, to the lowest grade, where even moderate alcoholic indulgence implies diminution of other food supplies; further, their excesses are, as a rule, persistent and intense. Again, it is an unquestionable fact that in the criminal and in the insane alcoholic the nervous manifestations of intoxication occur with notable frequency, while non-nervous disorders are relatively rare and secondary. Thus, in the cases comprised in this inquiry the special nervous localization of the poison was very marked.

Thirty-one of the women had suffered from one or more attacks of alcoholic delirium, while twenty-four others, without actual delirium, had occasional visual hallucinations. Suicidal impulses, disorders of cutaneous sensibility, and cramp in the extremities were noted in a considerable number of cases. Similar characteristics were found to be present in the case of alcoholic relatives of the patient. Of 120 female inebriates whose histories were trustworthy there were born 600 children, of whom 265 (44.2 per cent) lived over two years, while 335 children (55.8 per cent) died when under two years of age, or were still-born. With a view to establishing comparisons with a healthy non-alcoholic standard, it was found that 21 of the women were able to give details regarding female relatives (sisters or daughters) of sober habits who had contracted marriages with sober males and had borne children. Thus, of sober mothers, 28 in number, there were born 133 children, of whom 33 (23.9 per cent) died when under two years of age. Thus the death-rate amongst the children of
the inebriate mothers was nearly two and a half times as great as that amongst the infants of sober women of the same stock.

Another feature established by the observations was the progressive death-rate in the alcoholic families when three or more children were born. This will be best seen from the following table:

<table>
<thead>
<tr>
<th>Cases</th>
<th>Dead and Still-born. Per cent.</th>

<tr>
<td>Sixth- to tenth-born</td>
<td>93</td>
</tr>
</tbody>
</table>

These figures illustrate very clearly the progressively augmenting results of the influence of the mother’s alcoholism on the offspring. The type of alcoholic family suggested by these results—a type characterized by decrease of vitality in the successive children—is fully realized in many of the observations, of which the following is an instance: S., aged thirty-four years; previous imprisonments 41. Drunkard since first confinement; beer and spirits. Suffers from gastric catarrh and cramps; had one attack of delirium tremens. Attempted suicide twice; hysterical convulsions. Husband, drunkard; never delirious. His and her parents sober. Six children; first, second, and third living, healthy; fourth, aged six years, of low intelligence, habits bad; fifth, aged four years, epileptic idiot; sixth, still-born; seventh, a recent abortion. In other cases we find the first-born healthy, one or two of the next dying from infantile convulsions, and the last child or two still-born.

Of the children comprised in the series 219 lived beyond infancy, and of these nine, or 4.1 per cent, became epileptic—a proportion extremely high as compared with the frequency of epilepsy in the general mass of population, which, according to Bruce Thompson, is less than 1 per 1000.—London Lancet, Sept. 30, 1899.

THE PREVENTION OF SICKNESS AFTER ANESTHETICS.

Blumfeld, in the London Lancet of September 23, 1899, says that some of the chief points to be attended to in the avoidance of after-sickness are: (1) Use as little of the anesthetic as possible consistent with perfect anesthesia; (2) wash out the stomach at the close of the operation when much mucus has been swallowed; (3) in long operations substitute chloroform for ether after three-quarters of an hour; (4) move the patient about as little as possible during and after operation; (5) place him on his right side in bed with the head only slightly raised; (6) give nothing but hot, thin liquids in small quantity for at least eight hours after; and (7) do not alter the temperature of the room for some hours. With proper attention to these points one-third of the patients operated on will be free from after-sickness, and for short operations the proportion will be much higher still. In fact, after all administrations up to twenty minutes, or not much longer, sickness will be found to be the exception.

THE TREATMENT OF TUBERCULOSIS BY CINNAMIC ACID.

Professor Landerer, of Stuttgart, has published a volume of three hundred pages in which he gives his methods and results in the treatment of tuberculosis by cinnamic acid. His experiments have extended over fifteen years and have been employed in 240 cases in the Sanatorium at Leysin. He believes that cinnamic acid produces an intense phagocytosis, causes a sclerotic condition of the tissues in the neighborhood of the morbid process, thereby circumscribing it, and that it also exercises a germicidal influence upon the bacillus. Cinnamic acid occurs in small, colorless, and odorless crystals, insoluble in cold water, somewhat soluble in hot water, and very soluble in alcohol and ether. The cinnamate of sodium is a white crystal powder soluble in hot water in the proportion of 1:20. Landerer has employed the cinnamate of sodium in the form of a solution or emulsion. The strength of the solution varies from one to five per cent, and the reaction is made neutral or strongly alkaline. The solution before it is employed is filtered, and sterilized by boiling for five minutes. The formula employed is as follows:

- Finely powdered cinnamic acid, 7 grains;
- Oil of sweet almonds, 150 minims;
- Yolk of an egg, 1;
- Saline solution, 7 per 1000.

A sufficient quantity to make 3½ ounces.

This preparation is introduced into the body by intravenous or intramuscular injections. A vein is bandaged in such a way as to make it stand out well, owing to constriction, careful antiseptic precautions are used, and fifteen to thirty minims of the liquid
is injected into the vein, after which the needle is withdrawn and a small compress is applied. As a rule the injections at first must be given in very small quantities, one-sixtieth to one-thirtieth of a grain of cinnamic acid being usually enough to begin with. Larger doses are finally employed, but nothing in excess of a third of a grain is ever given. When intramuscular injections are used, slightly larger amounts may be given at the beginning dose. The injections are repeated every two to four days, according to the state of the patient. [We do not believe that it is safe to inject oil of sweet almonds into a vein, since oils injected into veins are very apt to produce emboli.—Ed.]

Landerer claims to have obtained the following results: In 110 cases of pulmonary tuberculosis of different degrees he got 57 cures, 26 improvements, 5 unsuccessful cases, and 22 deaths. In 72 patients suffering from tubercular arthritis he got 59 cures, 8 improvements, 2 unsuccessful cases, and 3 deaths. In 48 cases of glandular tuberculosis he had 17 cures and 1 improvement. In 20 cases suffering from peritoneal tuberculosis he got 16 cures, 2 deaths, and 2 patients in whom no change was appreciable. In 5 cases of urinary tuberculosis he got 3 cures and 2 deaths. In 3 cases of tuberculosis of the testicle 1 cure, and in the other two cases no results were appreciable. He therefore considers that his method of treatment is really specific to a great extent.—Journal des Praticiens, October, 1899.

THE PROGRESS OF MEDICINE IN THE NINETEENTH CENTURY.

Dr. Frederick J. Roberts, in the course of an address before the Medical Society of London, which is published in The Lancet of October 14, 1899, tells us that a distinct advance in practical therapeutics which must not be forgotten as a development of this century is in the modes of administration of therapeutic agents, the preparations and appliances intended for local purposes, and the instruments or apparatus invented for making applications to, or otherwise treating, special parts. At the present day a visit to the exhibition usually arranged for our edification at the annual meeting of the British Medical Association and at various congresses is a revelation as to what has been and is being accomplished in this direction, in which, of course, our profession is greatly aided by pharmacists and instrument-makers. Reference may be made to the many palatable, convenient, compact, and elegant preparations given to us by pharmaceutical chemists for internal administration, in contrast with the boluses, powders, electuates, and horribly nauseous draughts and mixtures of the old pharmacy; and to the introduction of the hypodermic syringe, the value of which to the practitioner can hardly be overestimated. Undoubtedly there are serious drawbacks associated with these advances which we must never ignore, and these are the facility with which the laity can now get strong drugs in convenient forms for their own use without any medical supervision, and the danger of falling into the habit of using powerful subcutaneous injections, which has done, and is still doing, such serious mischief, not only amongst patients but also to members of our own profession, a fact which is but too familiar.

During the earlier part of this century, and indeed until within a comparatively recent period, treatment consisted almost entirely of the use of drugs in different ways. By degrees the great principles of hygienic treatment took hold of the profession and the public, and they are now well to the fore and highly popular, at any rate in theory. Surely this is a great step in advance in practical therapeutics, and nowadays, apart from the more obvious general hygienic measures, the means for carrying out some of the most important of these principles, such as change of air, suitable climate, sea voyages, the use of baths, and the like, are so increased and improved, and so much within the reach of large numbers of the community, even to some extent among the poorer classes, that there is no excuse for neglecting them. Diet, too, has come to occupy a far more conspicuous place in treatment than formerly, and is regulated on more scientific principles, certainly to the general advantage, though there is, perhaps, a tendency in the profession on the whole to make more of questions relating to food and drink than seems absolutely necessary, which renders it very difficult to deal with not a few patients who, being quite "up-to-date," expect to receive the most explicit directions as to diet under every conceivable circumstance, and suitable for every complaint, real or supposed, from which they may happen to suffer. And what shall be said about nursing, which to-day is so universally and rightly regarded as one of the most important and essential parts of modern treatment? Some of us must have
a vivid recollection of the hospital nurse of former days, who was as incompetent as she was unattractive and insanitary, and of the time when private nursing as it now exists was practically unknown. The progress that has been made in this department is simply amazing, and those who are only familiar with the present state of things can have no possible conception of the magnitude of the changes which have taken place during the last thirty or forty years, and of the comparative advantages in the way of capable and reliable nursing which modern treatment affords.

A conspicuous, and within due limits really serviceable, development of modern therapeutics is the introduction or more systematic working-out of what may be termed "special methods" or "combinations of methods," which are still being added to, and intended either for the purpose of producing some particular effect which might be beneficial in various conditions, or for the treatment of some individual disease or class of diseases. It would be quite out of place to attempt even to enumerate these methods here; but they are not all really novel, some being the revival of methods formerly practiced, or the application, more or less elaborately, of well-known physical principles. Others, however, are the natural outcome of the more or less modern discovery of forces, or elements, or facts previously unknown, which under judicious and intelligent guidance have been found to be highly valuable in treatment when properly employed. Others, again, are essentially recent and original, especially those which we owe to the truly astonishing and far-reaching results of investigation and research in relation to bacteriology and kindred subjects.

Taking a comprehensive view of these modern methods, they certainly are so far to be commended that they present a practical protest against the needless and excessive use of drugs which, when rationally and honestly employed, are often of unquestionable advantage in treatment. Some of them give evidence of the possession, on the part of those who are responsible for their introduction to the profession or their practical working, of considerable ingenuity and inventive ability; others of a profound knowledge of human nature. It is a pity that they afford excellent opportunities for the most outrageous quacks outside the profession to enrich themselves at the expense of the idiotic sim-pletons who are still found in such large numbers even in this highly educated and enlightened age. Of this statement glaring and really ludicrous examples could be given. But what can we expect when so many men and women of intellect and culture, aggressively scientific, will to-day throw over everything that is orthodox in our profession and pin their faith upon any system, however pretentious and absurd it may be, which gives itself a high-sounding name, and will even prostrate themselves before the Christian Scientist!

THE TREATMENT OF WHOOPING-COUGH.

The Journal des Praticiens of September 30, 1899, gives the following summary of various methods which may be employed in the treatment of this affection. One method is that of Dutremblay. It consists in treating the disease by inhalations of oxygen gas saturated with medicated vapor. In a dilatation of the tube through which the oxygen gas passes is placed a piece of cotton, and this cotton is wet with equal parts of bromiform and cherry-laurel water. In other cases it is wet with a solution of bromated camphor.

Gilbert has suggested that whooping-cough be treated by antiphilheretic serum, and claims that when this serum is injected as it would be for the cure of diphtheria, it does good in whooping-cough, perhaps by producing leucocytosis. He claims that Cerioli, in an epidemic of whooping-cough, treated fifteen cases in this way with very satisfactory results in all except one. The dose injected was from five to ten cubic centimeters, but the strength of the antitoxin is not given.

A third way of treating the disease is that by Legrand, who has found Grindelia robusta a most efficient remedy in whooping-cough as well as in asthma. He believes that the powdered bark and its fluid extract are apt to be inactive, but that the tincture is useful, and that the alcoholic fluid extract is also valuable. He has usually administered the fluid extract in sugared water or milk, although there is always a certain amount of the resinous material precipitated in the vessel from which the child takes the dose. This may, to a certain extent, be avoided by adding to the milk a little glycerin and alcohol. Children should take eight minims of the extract every few hours according to the effect produced.
REPORTS ON THERAPEUTIC PROGRESS.

INTESTINAL STRANGULATION BY MECKEL'S DIVERTICULUM.

Bérand and Delore (Revue de Chirurgie, No. 6, 1899) have quoted thirty-two cases in which operation was performed for the relief of intestinal obstruction due to strangulation by Meckel's diverticulum. Twenty-three of these patients died and nine recovered. The usual cause of death was septic peritonitis, which in turn was due to delay in operation.

THE TREATMENT OF PERSISTENT ARTHRALKIA BY RESECTION.

Ollier (Revue de Chirurgie, No. 9, 1899) reports a number of cases of persistent and crippling arthralgia successfully treated by joint resection. He holds that the question as to the advisability of surgical intervention under such circumstances is one which is extremely difficult to determine. Moreover, the diagnosis is often obscured by hysteria.

Of the four cases which Ollier reports, all were young women; in two the shoulder was resected, in two the knee. In all the lesions found on opening the joint were not in the slightest degree commensurate to the degree and severity of the pain.

The first patient, after traumatism, suffered the most agonizing pain in her shoulder. After four months' immobilization and revulsion without any benefit, the joint was resected. The bone was perfectly sound, but the cartilage was congested. The pain was relieved immediately, and the wound healed, leaving a perfectly functional joint. Seven years later this patient died of tuberculosis. In two other cases the affection began with slight trauma. In the fourth case it began apparently as a rheumatic joint.

ACUTE INTESTINAL OBSTRUCTION FROM IMPACTION OF GALL-STONE IN THE UPPER PART OF THE JEJUNUM CURED BY ENTEROTOMY.

Stirling (Intercolonial Medical Journal of Australasia, No. 9, 1899) operated on a man sixty-eight years old for the relief of a sudden attack of pain and vomiting. He had had one previous attack of biliary colic. There was marked shock. The vomiting was fecal in character, and constipation was absolute. As soon as the abdominal cavity was opened, a gall-stone was recognized in the lower part of the jejunum. This was removed, and the bowel was closed with Lem-bert sutures. The abdominal wound became infected and was opened. Afterward the patient healed without accident. Two other cases of acute intestinal obstruction from impacted gall-stone occurred in the Melbourne Hospital within the author's recollection. Both cases died—one from gangrene of the intestine, and the other from general peritonitis.

SECTION OF THE SYMPATHETIC IN THE TREATMENT OF EPILEPSY.

Laborde (Therapeutische Monatshefte, Heft 10, 1899) states that when epilepsy has been artificially produced in guinea-pigs, either by section of the sciatic or half section of the spinal cord, cutting the sympathetic has no curative effect upon this epilepsy. Déjerine, in commenting upon this observation, holds that it accords strictly with clinical observation, since a case on which he had operated for the cure of epilepsy by cutting the sympathetic exhibited afterward both increased violence and increased frequency of the attacks.

TREATMENT OF CHRONIC URETHRITIS BY INSTILLATIONS OF PICRIC ACID.

Desnos and Guillou (Journal de Médecine de Paris, No. 41, 1899) assert that picric acid exerts an almost specific action in the cure of chronic urethritis. Although this drug when employed for the cure of extensive burns has more than once produced symptoms of poisoning, its toxic properties are comparatively so mild that it is impossible to inject into the urethra a quantity sufficient to cause constitutional symptoms. The solutions stain the fingers, but the stain is rapidly removed by soap and water, whilst the color can be removed from fabrics by the employment of diluted solutions of ammonia or potassium. The instillations are accomplished by means of a syringe holding about eighty drops of the solution. This is adjusted to a hard catheter with a fine lumen. The latter is introduced to the compressor urethra muscle, and the solution is driven in gently until it flows out at the meatus.

The posterior urethra is treated by introducing the end of the catheter through the compressor muscle and injecting as before, the fluid then flowing into the bladder. This latter viscus must, of course, have been emptied before the instillation is made.

The strength of the solution varies from 1
to 200 and 1 to 100. The quantity employed varies from twenty to eighty drops. Very little pain is experienced as a result of these injections, and this quickly passes off, nor is the reaction characterized by an uncontrollable desire to urinate, and the reappearance of a free discharge. The authors have treated only twenty-nine cases of chronic urethritis. In twelve the infection was tubercular, in seventeen it was due to other microorganisms. These cases were such as had proved intractable to the careful and scientific employment of the ordinary medicaments, such as protargol, silver nitrate, copper sulphate, etc.; and indeed the claim is made for picric acid that it is especially serviceable under such circumstances. The coeci were few, and the discharge so slight as to be perceptible only after debauch. The duration of the treatment has varied from two weeks to five months. In general, from sixteen to seventeen treatments were sufficient.

Of the seventeen cases of simple chronic urethritis, thirteen were definitely cured, two were markedly helped, and two experienced no benefit; one of these latter was afterward cured by urethrotyomy, and the other by instillations of protargol. Of the twelve tubercular cases, two were cured, seven were benefited, two were made worse, and one showed no effect.

ONE THOUSAND AND ONE LAPAROTOMIES.

Sneguirreff (Revue de Chirurgie, No. 9, 1899) takes much joy in the thought that of his 1001 cases he has not caused death in a single instance by either sponges or instruments being left in the abdominal cavity. He states that airy persiflage and brisk conversation is unseemly in the operating-room, because thus may be confused those persons to whom is entrusted the count of the sponges and instruments. Ninety-eight of his patients died, a mortality a little under ten per cent. It is to be noted that exploratory laparotomy, which was performed twenty-four times, gives a mortality of sixteen per cent, while supravaginal hysterectomy is credited with a mortality of over seventeen per cent. Thirty-nine cases died of septic infection, thirteen of internal hemorrhage, eighteen of shock and of paralysis of the heart, and only two of pleurisy or pneumonia.

Secondary laparotomies were performed for intestinal occlusion in eleven cases, three of which died; for anuria in two cases, one of which died; in cases of fear that sponges or instruments had been left in the belly in two other cases, one of which died. It is interesting to note that in 1889 the author operated on 101 cases, and in 1899 on a similar number, thus not showing that increasing capacity for geometrical increase often noted in the modern laparotomist.

In 1896 the author was using catgut prepared in the ordinary manner and with perfect satisfaction, when suddenly three septic cases developed, in which infection was shown by the autopsy to have started in the ligatures. Until 1896 sponges were used, since that time gauze. The author remarks that since using a proper sterilization there was a rapid diminution in mortality. In the last year, of ninety-eight cases of laparotomy but a single one died; death in this case was due to pneumonia and cardiac palsy. It is noteworthy that llysol is used in cleaning the wounds, that tendon is employed for ligatures and buried sutures, and that the instruments are boiled in water. Saline solution is used liberally, not only for its cleansing purposes, but also as a hemostatic and as a means of finding the source of a bleeding. Iodoform gauze is used liberally, and firm faith is placed in drainage; indeed, drainage has been used in nearly half of the cases, and the author naively remarks that the hernias were due not to the drainage but to other circumstances.

CONGENITAL IDIOPATHIC DILATATION OF THE COLON.

Griffith (American Journal of Medical Sciences, September, 1899) reports a case of fatal idiopathic dilatation of the colon occurring in a boy about three years old who had been troubled from birth by persistent constipation, and who had a progressive distention of the abdomen from his fifth month. Right inguinal colotomy was performed, but the child perished of exhaustion. There follows a careful study of the literature bearing on this subject.

Griffith states that the degree of dilatation of the colon had been often enormous. It has sometimes appeared at autopsy to fill the whole abdominal cavity, crowding everything else out of sight. A very characteristic pathological feature has been the thickening of the walls of the colon. This has been reported in nearly every case. Only in Formad's is it stated to have been absent. In a
few others it is not referred to. Generisch is disposed to regard the thickening as an early change, and as one of the causes of the loss of peristaltic power. It seems, however, just as likely that it is a later change occurring in an effort at compensation. Ulceration of the mucous membrane is another alteration quite often seen. It is doubtless a later change and not a necessary one. It was nearly always found in cases in which severe diarrhea had terminated life.

The diagnosis is easily deduced from the symptoms. It rests upon the very early presence of troublesome constipation; the development with this, soon after, or rarely before, of great tympanic abdominal distention; the discovery often of the distended colon outlined through the abdominal walls; the absence of evidence that the constipation is due to impaction; the absence of any discoverable organic obstructive cause, as shown by the exploration of the rectum and colon; the absence of any previous debilitated state of health which might occasion colonic atony; and, finally, the confirmation by an autopsy that no structural obstruction of the intestine was present. This last, although, of course, a "post-mortem diagnosis," is often indispensable. A sharp diagnostic line between idiopathic and obstructive congenital cases cannot always be drawn.

Treatment can only be (1) hygienic and medicinal, and (2) operative. In the first class improvement of the general health is indicated, since this may help to increase the peristaltic power of the colon. Massage has been recommended by some, and condemned by others on the ground that it may produce perforation of ulcerated spots. Carefully performed in cases without diarrhea or tenderness, it seems indicated. Electricity may be used for the same purpose. Means must be employed to empty the bowels either by purgatives or enemata. Objections exist to the use of either, since eventually they tend to weaken still further the muscular power. In the case of Hughes the child seemed to be made distinctly worse by enemata. Yet it is often a case of "needs must," and that remedy has to be selected which best unloads the bowels and gives relief. The use of the rectal tube to remove gas has sometimes been a great comfort to the patient. In three instances—Martin's, Hobbs', and de Richmond's, and one of Hirschsprung's—puncture of the intestine with a fine trocar has been performed, in order to allow gas to escape.

In any severe case tending to grow worse seasonably early operation of some sort is to be advised. In spite of the gravity of the procedure, not to employ it seems still more grave. Exploratory laparotomy was performed on the patients of Fütterer and Martin, but nothing more radical was attempted. An artificial anus was made by Halsted in Osler's case, and the child recovered. The operation done by Treves on a child with dilatation consequent to congenital stenosis might well be employed in idiopathic cases—viz., the entire removal of the functionally useless dilated colon and the joining of the small intestine with the anus. As this is a serious operation the attempt to relieve the dilatation by the formation of an artificial anus may well be made first.

**SURGICAL TREATMENT OF DUODENAL ULCER.**

Pagenstecher (Deutsche Zeitschrift für Chirurgie, 52 Band, 5-6 Heft) states that duodenal ulcer should be treated on the lines applicable to the treatment of gastric ulcer. The indications for operation are also similar in the two cases; thus, persistent dyspepsia, pain, vomiting, repeated and exhaustive bleeding, and the symptoms of acute perforation all indicate operation. Moreover, dilatation of the stomach, secondary to duodenal ulcer, and encapsulated abscess, also require surgical intervention. Perforation usually takes place in the peritoneal cavity. The symptoms are either those of generalized sepsis, suppuring abscess, peritonitis, such as follows perforation of the stomach, or of a suppuration or perforation of the gall-bladder.

The author quoted twenty-eight cases of operation with a mortality of nearly eighty-six per cent. In only twelve cases was the perforation found; eight of these died. Bleeding is one of the most constant symptoms of duodenal ulcer; it appears both in the vomit and in the stools. Cachexia, associated with a wasting pain, indigestion, and vomiting, is present, and is as pronounced as in ulcer of the stomach. The differential diagnosis of the two affections is, as a rule, quite impossible. Perry, of seventy cases treated medically and showing on section either ulcers or the scars of ulcers, states that twenty died of these ulcers, and in only eight was there cure, or 10.4 per cent. Of twenty-eight perforating ulcers treated surgically, twenty-four died. Of five cases operated on
during the florid period of the ulcer, one died after three months, and autopsy showed that the ulcer was healed; the remaining four lived and exhibited no further symptoms of ulceration. Of four cases operated on because of cicatricial stenosis, one died of operation, and the remaining two lived and remained well.

**The Treatment of Gunshot Wounds of the Mid-Dorsal Region.**

Auscaler (Revue de Chirurgie, Sept. 1, 1899) calls attention to the difference in vulnerating effect between the pistols commonly sold in the shops and the modern weapons which throw bullets of small caliber at high velocities. In the former case the moderate penetration of the bullet allows it to rest either in the soft parts or against the bony prominences of the spinal column without other risk than that of secondary abscess and resultant infection, whilst the modern bullet striking the transverse process of the vertebra would not only shatter it into many pieces and destroy the cord, but would necessarily carry many fragments literally by the hundred into the thoracic cavity in front. Moreover, there is immediate paraplegia. If this latter symptom is absent the prognosis is much more favorable. The absence of paralysis does not, however, prove that the vertebrae have not been injured. Thus, Chipault records the case of a man struck by a revolver ball in the body of the third cervical vertebra. The ball glanced downward into the mediastinum, causing an abscess from which the man perished two months afterward. Immediately after the injury this patient walked over seven miles.

It is possible for a patient to drop instantly paralyzed by a gunshot wound without injury to the spine, or to remain standing in spite of fracture of the vertebra. Cure is exceptional when paraplegia develops, since it is customarily a sign of section of the cord. It is, of course, always possible that the ball has penetrated to and not through the cord and produced paralysis by its direct pressure; under such circumstances an exploratory operation is indicated, by means of which the bullet may be removed, together with the broken splinters of bone pressing upon the cord.

Where there is no paralysis it may be taken for granted that in the majority of cases there is either no fracture of the vertebra or, at the most, a lateral or spinous process is involved. The ball may have penetrated into the medias-

**New Methods of Exploration Applied to Diagnosis of Renal Calculi.**

Albarran (Annales des Maladies des Organs Génito-Urinaire, No. 7, 1899) exhibited an x-ray photograph of a renal calculus, the first he had been able to obtain in the living, and narrated the history of a man twenty-eight years old, who entered the hospital because of symptoms of vesical irritability. This patient gave a history of repeated urethral infection, and had turbid urine for many years. Six years before he suffered from very severe renal pains, particularly marked on the left side, and lasting for several days at a time, but not assuming the characteristics of renal colic. Two years after this he suffered from occasional attacks of hematuria, following violent exercise, and especially horseback riding. This was allayed by rest. During two years of active campaigning he lost all his symptoms, but having been attacked by typhoid fever he developed a frequent and painful micturition, which became progressively worse until he was forced to seek surgical help.

A careful examination eliminated urethral or prostatic causes. The bladder was extremely sensitive, and its capacity was mark-
edly diminished, but no stone could be found by the searcher. There was no pain in the renal region, either spontaneous or excited by pressure.

Pyuria was constantly present. The diagnosis was evidently one of cystitis and pyelonephritis. The history proved conclusively that the infection started in the kidney. The pyelonephritis was evidenced by a purulent polyuria, the total quantity sometimes reaching seven pints, and by the chemical composition of the elimination; moreover by the passing blood which was found in the urine, as it escaped from the ureters. This was determined by introducing a catheter into the bladder, and washing this viscus thoroughly. The first urine which escaped from the catheter after this washing was turbid. But three hypotheses as to diagnosis were possible—the affection was either a simple, a tubercular, or a calculus pyelonephritis. The absence of tubercle bacilli, and of other signs or symptoms of tuberculosis, practically excluded this affection, whilst the aggravation of the bleeding, incident to exercise, strongly suggested calculus. This diagnosis was a probable, not an absolute, one, and moreover the affected side still remained to be determined.

The modern instruments employed for this service are the phonendoscope, which Albarran states has failed in his service, even when employed by Bianchi himself, in one out of two cases, and the cystoscope, which is much more to be trusted, since it enables the surgeon to inspect the ureteral orifices, and to observe the regularity with which the urine jets from them. In the normal state this jet is observed about every thirty seconds. Its rhythm may be greatly altered by disease, and the presence of blood or pus coming from one or the other kidney may thus be determined. The especial use of the cystoscope is, however, to facilitate catheterism of the ureters. This, in very exceptional cases, enables the renal stone to be felt with the searcher. Usually, even though a stone be present, the searcher fails to reveal its presence. Such catheterism should never be practiced when there is cystitis. If it is practiced, the bladder must be fairly capacious, which it was not in the case reported.

In this instance the Roentgen ray furnished the deciding proof. Uric acid calculi are most permeable to the Roentgen ray, the oxalates the most opaque.

Albarran cites most of the published cases of x-ray photographs of renal calculi, including those reported by Leonard, and has appended to his paper a picture of his own case, unusually clear in detail. He states that the radiograph will demonstrate perfectly oxalate calculi, which are the rarest of the common varieties. It will also show the presence of the phosphates and carbonates, but if Leonard's case be excepted, it has always failed to demonstrate the uric acid calculi and the urates. This is unfortunate, since the last mentioned calculi are under all circumstances the most difficult to diagnose, and are the ones which commonly lead to error in treatment. The absence of a shadow of a calculus in a carefully taken x-ray picture by no means excludes the possibility of a calculus existing in the kidney.

OSTEOARTHRITIS OF THE SPINE: SPONDYLITIS DEFORMANS.

Goldthwait (Boston Medical and Surgical Journal, Aug. 19, 1899) uses the term osteoarthritis to designate the disease of the articulations which is characterized pathologically by a marked proliferation of the edges of the articular cartilage, associated with an atrophy or degeneration of the cartilage at the points of pressure, the two conditions producing an amount of impairment of function of the joint varying from the slightest inconvenience to complete ankylosis.

The disease has been described by various writers in journal articles, but as yet there has been but slight mention of the subject in the works on orthopedic surgery, and most of the literature is devoted to the report of individual cases, with but little consideration of the disease itself.

Goldthwait has seen ten cases, which, with the thirty-five cases previously reported, make a sufficient number for analysis; but before this can be done these cases must be distinctly differentiated from the other type of rheumatoid disease, which is chronic in character and also leads to joint ankylosis, but in which there is atrophy of all the joint structures with no tendency to nodular growth or osseous deposit, as is seen in the type of disease under consideration.

Both of these diseases are usually considered together in the text-books under the head of arthritis deformans, which accounts for the variation in the clinical picture as it is presented by the various writers.

As the cases are seen side by side there cannot be the slightest question but what there are two distinct diseases, or two very
widely divergent types of the same disease, and it is because of this that much of the confusion has arisen.

In a paper published in the British Medical Journal, Bannatyne and Vollman have carefully described the two types, and in a paper entitled the "Treatment of Joints Disabled by the So-called Rheumatoid Diseases," published by Goldthwait in the Boston Medical and Surgical Journal of January 29, 1897, the two types were described and illustrated. In that paper the descriptive term "arthritis deformans" was used to designate the whole class of these so-called rheumatoid diseases. Rheumatoid arthritis was used to designate the cases in which joint inflammation and atrophy, resulting in ankylosis and marked distortion, were the chief features, while osteoarthritis was the term used for the cases in which the nodular deposits about the articulations were the most prominent features.

The importance of this differentiation is mentioned because several of the cases which have been published as spondylitis deformans are undoubtedly cases of rheumatoid arthritis, and are not osteoarthritis.

It is evident in the first place, in the analysis of the cases, that the disease is essentially a disease of adult life, but not necessarily a disease of old age, as is often stated. Some of the worst cases have developed in the period of late adolescence, while in very few has the process started in old age. The disease as it is seen in old age is not so definitely localized in the spine, but as a rule the other joints are also more or less involved.

Another feature which is also noticeable is that there is no one cause or definitely recognized etiology to explain the onset. Gonorrhea has been mentioned as a probable cause in a certain number of instances, but in a much larger number this is not suggested as a possibility. In the majority of cases the cause seems to be some exposure, or the rapid change in temperature of the affected part.

Still another thing which is evident is that the disease is not peculiar to this generation, and that it also is not peculiar to the human race.

Pathologically the disease consists of a nodular enlargement of the edges of the articular cartilages, with the subsequent ossification of these nodes and an extension of the process into the ligaments which have their origin or insertion near-by. With this hypertrophy at the edges of the cartilage the centers or areas of pressure usually undergo atrophy. In the atrophy the interstitial tissue is the last to be absorbed, which explains the granular appearance as it is seen at times, but as the process continues this interstitial substance is absorbed, and either the two surfaces of bone fuse or remain in apposition. In the other joints in which there is free motion the bare surfaces of bone frequently become polished and increase in density.

The process in the spine usually begins upon one side anteriorly and extends up or down along the anterior lateral ligament. It may remain as a comparatively local process involving only a small portion of the ligament, or it may cross over to the other side and extend up and down until the whole spine is invaded. When this occurs the chief deposit or new formation of bone is along the lateral ligament, the change in the median line consisting simply of a fusion of the vertebrae.

At times, even though the hypertrophic change is quite active, that which develops from adjoining vertebrae does not fuse, and a more or less free joint remains.

As the disease goes on in the ligaments and cartilages the intervertebral substances atrophy, and if the process is slow the entire intervertebral disk may be absorbed before ankylosis takes place.

When these changes are taking place in the anterior portion of the spine, similar changes take place in the ligaments and articulations at the back, so that the transverse and rarely the spinous processes are affected. It is the disease in these regions that causes most of the symptoms of paralysis or disturbed sensation, by narrowing the foramina through which the spinal nerves pass.

Clinically, as the disease is seen, the subjective symptoms are usually slight in comparison to the actual pathological change, and frequently there has been so little trouble with the back, and the change has taken place so gradually, that the patient is not conscious of any special limitation, the condition being discovered by accident. More often, however, there is considerable pain, which is referred to the back, and which is aggravated by change of position. When quiet the pain is so much relieved that the patient frequently does not seek treatment until the disease is far advanced, or even if treatment is asked it is often excused without examination as a "touch of rheumatism," and the therapeutic suggestions made accordingly.

If the disease is seen early, before much
actual change has taken place, there is usually a definite region in the spine to which the pain is referred, and in this region the motions are restricted, at first, of course, by muscular spasm, but later by osseous change. At this time, when the process is so definitely localized, the portion of the spine affected may appear more prominent than normal, suggesting the beginning deformity of Pott's disease, and a positive diagnosis may not be possible. The onset is suggestive, and also the reference of the pain to the back at the exact seat of the disease rather than the referred or abdominal pain of Pott's disease, but it may require some weeks before the true nature of the process can be determined.

As the ankylosis of the spine takes place the ribs almost invariably are affected, and the process may prove so extensive that all the articulations become ankylosed, and the thorax is perfectly rigid. In this case thoracic respiration is of course entirely lost, and the breathing is done wholly by the diaphragm.

Beside the pain in the back and the limitation of motion, neuralgic pains in the arms or legs, together with disturbances of sensation, numbness, or hyperesthesia, are probably the most common symptoms. These are, of course, due to pressure upon the nerve roots, and consequently are not seen until the disease is well advanced, or when the onset has been unusually rapid. Rarely are the two sides affected equally, or if both sides are affected the symptoms have developed at different times. This, together with the fact that the paralysis is peripheral in type, is of importance in differentiating it from Pott's paraplegia.

Occasionally, when the disease is very active, the same osseous deposit takes place in the posterior ligament (ligamentum longitudinale posticum), and may result in enough narrowing of the spinal canal to produce symptoms of pressure paralysis, exactly similar to that seen in connection with Pott's disease. This is not very common, but nevertheless does occur and must be borne in mind in making the diagnosis.

After the active stage of the disease has passed, with the lessened vascularity, and natural shrinking of the non-osseous structures, the direct pressure upon the spinal cord is usually relieved, and the same may be true of the pressure upon the nerve roots.

The deformity, which is so striking at times, has a wide range of variation. In the most extreme form the rounded back with the protruded head and the flat chest is the type usually pictured or described. It is evident, however, that the nature or extent of the deformity must vary with the seat or extent of the disease, and also with the rapidity of its development.

A moderate amount of lateral deformity is not uncommon, and is almost always present when the disease is in the cervical region.

The treatment of this disease is of more importance than is commonly supposed, and is partly medicinal and partly mechanical. As an early diagnosis is, of course, of the first importance, it is at this time, before the deformity has taken place, that the most can be accomplished. The disease is probably a trophic process, and consequently all medicines or methods of treatment which debilitate should be most carefully avoided. This naturally includes the various so-called rheumatic remedies, all of which are depressants, and also the various baths or courses of treatment which tend to lower the vitality. The general treatment should be wholly nourishing and stimulating. Extra diet, stimulating bathing, massage of the unaffected parts, electricity in a mild current, all are of value; and also the dry heat, provided it is not used so frequently as to be debilitating, relieves the pain and does much good. For medicines, iron, arsenic, and strychnine are the drugs which are of the greatest value. Cod-liver oil and alcohol in medicinal doses are also useful. For mechanical treatment some form of spinal support should be used at once, partly to relieve the pain by restricting the motion, and partly to prevent the marked deformity from developing.

Manipulation of the spine is naturally of little value, and probably would result in more harm than good. Attempts have been made to forcibly break up the ankylosis, but they have been followed, as would be expected, by results which were not satisfactory.

MOULLIN ON THE APPLICATION OF THE ROENTGEN RAYS TO MEDICINE AND SURGERY.

MOULLIN, in addressing the Roentgen Society (Lancet, Aug. 19, 1899), stated that it was his first duty to clear the Roentgen rays of a stigma which has been thrown upon them, and which has in some measure tended to limit their sphere of usefulness. So far as regards the injuries, often of a very serious character, which have followed prolonged exposure to the discharge from a focus tube the events and discussions of the past year
go a long way towards proving that the Roentgen rays stand blameless. Whatever the cause, the effect is not to be laid to their charge. The ether waves, which we recognize as light and heat, are acknowledged by all to have great influence over the changes which take place in living tissues. The ultra-violet rays, it is known, are especially potent, and the discharge from a focus tube may be so powerful as to cause the death of the structures which are exposed to it. But not only is there no proof that the ether waves which possess this power are the same as those which can be made visible to us as Roentgen rays, but there is every reason to believe that they are of quite a different order. Screens which cut off one have no influence upon the other, and consequences which follow too close exposure may be prevented, or at least very greatly diminished, by the interposition of substances perfectly transparent to the Roentgen rays. These consequences, however, although they may not be due to the action of the Roentgen rays, have an interest peculiarly their own, and Moulin thinks that they have not yet received the attention which they deserve. He thinks that in a few years' time, or even in a few months—for everything in connection with the subject advances with startling rapidity—it is quite possible that the existence of the ether waves which produce these results will be regarded as a matter of scarcely less importance than the existence of the Roentgen rays themselves. These waves have scarcely been studied as yet. Their action has been dreaded and avoided rather than courted. Every attempt has been made to eliminate and get rid of them. But of their power to influence the processes of nutrition which take place in the tissues for good or for bad, according to their strength and mode of application, there can be no question, and although in the strict definition of the title of the Roentgen Society they may not come within its scope, Moulin could not help expressing the hope that the Society may be made sufficiently comprehensive to embrace them and their action as well as the Roentgen rays themselves.

Instances of the injurious power possessed by these ether waves when exposure has been too close or too prolonged will occur to every one. They are matters of common notoriety. Hairs die and fall out. The cells that line the hair follicles perish, and though as a rule the hair is regenerated, after a time the effect upon the surviving cells is shown by the weak and stunted appearance of the new growth, and by the fact that it is often white in color. The epidermis becomes dry and scaly in the same way. The nails are affected, and briefly, if the exposure is sufficiently close the nutrition of the nearest and most superficial structures is so impaired that they die and are thrown off. In the worst cases the effect extends more deeply still. Not merely the epidermis, but the corium and even the subcutaneous tissues perish, so that when the dead structures do separate at last the destruction may be so great as to necessitate amputation. There is no inflammation at any time. The effect is entirely different from that which is produced by light or heat or by the action of the ultra-violet rays. In the majority of instances no change of any kind is perceptible for upwards of three weeks. There is no alteration in the blood-supply or in the innervation of the part, no coldness or loss of sensibility. Doubtless the cells which form the walls of the smaller blood-vessels and the terminals of the nerves are affected like the other, but the death which follows is not due to cessation of the circulation or to defective innervation. Quietly and slowly, at the end of about three weeks, cell after cell perishes, layer after layer is thrown off, until at last a stratum is reached in which there is still sufficient vitality to enable the tissues, if everything else is favorable, to hold their own and to begin the process of repair.

Every case heretofore reported has been characterized by these peculiar features—features which distinguish these injuries from all others. There is first a long period of quiescence in which no change of any kind is apparent, a period of weeks. Then there is a period of decay and death, extending more or less deeply according to the duration and the closeness of the exposure, entirely uninfluenced by treatment. There is no evidence that anything in the way of active treatment has stayed the process in the least, though it is not improbable that it has sometimes made it worse. And this in its turn is succeeded by a period of repair, as slow and precarious as it is after an extensive frost-bite, the progress which has taken weeks to make often disappearing again entirely in the course of a few hours.

Such were the results obtained in the earlier cases—results not anticipated, and above all to be avoided. But because an agent at its first introduction, when its powers are entirely unknown, is found to
be of a most destructive character, it does not follow that when properly controlled and regulated it may not possess valuable properties of its own. And this appears to be true of these ether waves. Events and discussions of the past year have shown that the power which, uncontrolled, is able to destroy all that stands in its way, may be tempered in such a manner as to prove a valuable source of help. That bacteria living in the tissues can ever be destroyed by its agency, as they can be when growing in artificial cultures conducted under special conditions, is highly improbable. The power of resistance possessed by these minute organisms is as great as, or even greater than, that of the tissues themselves, and anything which tends to lower their vitality would lower the vitality of the tissues to at least an equal degree.

All hope, therefore, of destroying such organisms as the tubercle bacillus in the tissues must be laid on one side. But it has been shown that under the influence of these ether waves tissues which have been invaded by certain organisms and which were failing in the struggle may be so strengthened as to be able to cope with their invaders far better than they could before, and even in certain instances gain the upper hand without any other assistance. But there can be no doubt that cases of lupus and eczema have been cured by exposure to these waves, not the least successful having been those published in the Archives of the Society by Mr. Thurs-tan Holland, and that not only have they been cured, but that the scars left have been of a singularly inconspicuous character, showing that the destruction of the living cells had been reduced to the smallest limit consistent with repair. How far this action is capable of extension it is not possible to say at present. The whole thing is in its infancy. But no one can deny that in these ether waves we possess a power which can quietly and imperceptibly modify the processes which are constantly taking place in living cells in such a way that we can either stimulate them to increased energy or depress their vitality until they quietly and slowly perish.

The day may come when the existence of this power may prove of scarcely less importance than the discovery of the Roentgen rays themselves.

Immense improvements have been made in the course of the past year in the manufacture of tubes suited to the much more heavy discharges that are being used now, and in other technical details. Two especially stand out above the rest as of the highest practical importance in medicine and surgery, namely, the application of stereoscopy, by which localization has been rendered so much more easy and the relative position of deeply buried objects has been made visible; and, though it is far from probable that we have reached finality in this, the introduction of the Wehnelt break. The time of exposure even for such cases as renal calculi has been shortened from hours to minutes and even fractions of a minute. The risk of causing injury has altogether disappeared. Many operators can point to hundreds of cases which they have taken, not one of which has ever suffered the slightest harm. The illumination now is much more brilliant and more steady. Clearness of definition has been increased almost beyond expectation, and means have been devised by which photographs can be obtained of many of the soft structures in the body which were previously regarded as too transparent to throw any shadow. It is unhappily still true that a large proportion of the rays is wasted and lost, especially in taking photographs, and that a great deal of the detail is obscured in printing, so that the chief value is in the negative. In other words, we are not yet able to utilize to the full, or even nearly to the full, the light which we can produce. But there can be little doubt that in a short time these difficulties, too, will be overcome, and that then the results which we shall obtain will be as superior to our present ones as these are to those of two years ago.

The screen has now reached such a degree of perfection that with suitable apparatus the minutest movement of the heart and the lungs, and the least change in the action of the diaphragm, can be watched and studied at leisure in the living subject. Photographs of the most deeply buried bones can now be obtained without difficulty. Measurements of such structures as the pelvis can be taken directly by a simple process of calculation without subjecting the patient to the least inconvenience.

Many disorders which even after the discovery and the first application of the Roentgen rays were regarded as almost impossible of certain demonstration, such as aneurisms of the thoracic aorta, interlobar empyemata, mediastinal abscesses, and patches of central pneumonia, can now be shown upon the screen with the greatest distinctness and localized with absolute accuracy. Photographs can be taken of enlarged mediastinal
glands and of other intrathoracic growths. The illumination now is so steady and uniform that the earliest stages of tuberculous lesions in the lungs can be seen and recognized, partly by the curiously stippled shadows which they cast, partly by the visibly impaired movement which accompanies them, a fact which has not escaped the notice of some of those who are connected with life assurance. Cavities in the lungs, whether containing air or pus, can now be detected at once, and the position and depth from the surface can be accurately mapped out, so that the question of the advisability of drainage and operation is once more coming to the front. The presence of adhesions, the alteration in the level of pleural effusions in different positions of the body, the distinction between sub- and supra-diaphragmatic collections, and the existence of cysts or of tumors projecting from the upper surface of the liver and raising the diaphragm, can now be shown with the greatest clearness. And the same may be said of the changes in the position of the heart and in the size and shape of its chambers, whether brought about by disease or by strain thrown upon their walls by difficulties in connection with distant vessels. They can be seen distinctly with the screen and can be watched from day to day, especially easily in those cases in which owing to the presence of emphysema and the absence of cardiac dulness the ordinary tests fail to give any information. There is, in short, scarcely any change in connection with the lungs and the heart and the great vessels which cannot now be seen and photographed, scarcely a disease of the chest or of the organs which it contains concerning which the most valuable information cannot be obtained.

The benefit which surgery has derived from the improvements which have been effected in the use of the Roentgen rays during the past year is no less striking. Military surgery will have to be rewritten. Thanks to the ease with which suitably planned apparatus can be carried on campaign, all the wearisome and intensely painful probings after bullets and foreign bodies to which the wounded look forward with such dread have been swept away. The actual position of the bullet is defined at once, no matter how deeply buried it may be, and if removal is considered advisable it is cut down upon and extracted in accordance with well-defined anatomical principles, and the track that it has made is left to heal up of itself. Shot and other substances, such as portions of percussion caps, have not only been localized in the eye, but their exact shape and size have been ascertained with such high a degree of accuracy that they could be removed by the most direct route through the smallest possible incision. Bullets, the position of which inside the skull could not even be conjectured, have been successfully localized and extracted from the brain. Foreign bodies, such as plates of false teeth which have been swallowed accidentally, or worse still, have dropped into the air-passage; others, such as Murphy's button, introduced in the course of operation, splinters of bone, pins and needles of various kinds, wire sutures, fragments of glass which have been buried perhaps for years, and numberless other substances, have not only been made visible, but have been marked out as accurately as if they had been lying in some perfectly transparent medium, so that they could be excised or not according to the degree of inconvenience which they caused and the relative danger of the operation.

As might be expected, the largest proportion and the most striking cases have been furnished by the injuries and diseases of bones and joints. Those only who have experienced the difficulty of determining whether a fracture or a dislocation, or both together, may not be present in the neighborhood of such a joint as the elbow, when the soft tissues around are so swollen that no bony prominence of any kind can be felt, can realize the immense help given by a well-lit fluorescent screen. It is no question now of long exposure or of keeping the patient, perhaps a child frightened and suffering pain, quiet for a considerable part of an hour, or even under an anesthetic—half a minute is enough. The nature of the injury is apparent at once, and what is even more valuable, it is no less easy to ascertain whether the fracture is properly set or the dislocation completely reduced.

Diseases of bones and joints have benefited no less than injuries. Thanks to the improved methods of the past year the hip-joint can now be radiographed with certainty. All the strange appearances which were so misleading, and which were due in large measure to the distortion produced upon the photographic plates by faulty position, can be eliminated, and the various forms of congenital dislocation can be differentiated from each other and from such complaints as coxa vara, which are attended
by deformity of a somewhat similar character. The fate which overtakes bony grafts implanted into defects has been watched as plainly as if the grafts were on the surface of a limb instead of deeply buried in its substance. Diseases such as sarcoma, tuberculous deposits, central abscesses, necrosis, and the like, which when they occur in deeply seated bones are often exceedingly difficult to recognize and distinguish from each other, have been made perfectly plain. Cavities hitherto almost inaccessible without operation, such as the frontal and sphenoidal sinuses, have been brought within reach of the probe. Valuable help has been given in the diagnosis of antral and other maxillary tumors, and a serious blow has been inflicted upon the reputation of the bone-setter, who, now that the position of even the smallest bone can be shown to the patient in a photograph, has been compelled to alter his physi- ology if not his practice.

Renal calculi can be looked forward to with a fair degree of certainty, and what is even more valuable, as saving patients from unnecessary operation, the evidence can be trusted equally well when it is negative. In all ordinary cases it may be said that if no calculus is seen there is no calculus there to see. Unfortunately biliary calculi elude us still.

THE DANGERS OF REDUCING DISLOCATIONS OF THE SHOULDER BY THE FOOT-IN-THE-AXILLA METHOD.

Thomas (quoted in the Medical Review, vol. ii, No. 12) calls attention to the dangers of the “foot-in-the-axilla” method of the reduction of shoulder dislocations. Quoting some extremely instructive cases in corroboration of his statements, he notes, as sequelae of this method, almost total musculospinal paralysis (the exception being feeble extension of elbow and wrist); almost total median and ulnar paralysis; general atrophy of the muscles of the forearm and hand; trophic changes of the skin.

It has often been stated that the head of the displaced humerus presses on the brachial plexus, and produces loss of power in the muscles of the arm. In very severe injuries this, of course, may be so, but of all the dislocations reduced by the method of manipulation to be described, in not a single case were there paralytic symptoms. That pressure of the humeral head on the brachial plexus may occur during its absence from the glenoid cavity is admitted, but that this pressure hardly ever produces severe damage of the nerves in ordinary cases can be readily demonstrated by testing the power of the hand and elbow before reduction is attempted.

When the foot is placed in the axilla in dislocation of the humerus, it presses itself into an angle formed by the shaft of the humerus and the axillary border of the scapula, and produces pressure on the nerves of the brachial plexus, the nerves most liable to suffer being those nearest the bone, viz., circumflex and musculospinal nerves, these being contused against the humerus, some branches to the triceps generally escaping pressure; this accounts for the persistence of some triceps power. If the operator uses great force, then the median and ulnar nerves are damaged against the humerus. The amount of pressure used is more than is generally supposed. From a consideration of many cases, and an examination of the anatomical parts concerned, the writer has no hesitation in affirming that the foot-in-the-axilla method is responsible for these paralytic arms.

Why is the foot-in-the-axilla method so commonly resorted to? Apparently from frequent failure of the well known Kocher method of manipulation, in all but the extremely simple cases, where the head of the humerus has not traveled far inwards; for the utility of this method is undoubtedly limited, and it is only particularly applicable to the subcoracoid variety.

The following method of manipulation has answered very well in all the cases that have come under the writer’s observation in the past seven years, and has the advantage of being suitable to the subcoracoid, subglenoid, and subclavicular varieties of dislocation, and a slight modification of it would probably reduce a subspinal dislocation. It may be described as a combination of the “Kocher” and the “traction outward” methods.

The patient being seated on a firm stool or chair, an assistant stoops down on the left side, if the right shoulder is dislocated, and with his left arm crossing the front of the patient’s chest, places the hand firmly on the end of the right clavicle and acromion; his right arm is passed behind the patient’s back and grasps with hooked fingers the axillary border of the scapula. His function is to fix the scapula, and prevent the manipulator dragging the patient off the chair (occasion-
ally a second assistant becomes necessary to hold assistant number one, if the muscles of the patient are powerful, and traction by the surgeon has to be kept on long). The surgeon, keeping the elbow at a right angle, grasps the wrist of the dislocated arm with his right hand, and the lower end of the humerus from behind with his left hand, and locks this hand against the forearm of the patient to prevent slipping. He now quietly and slowly abducts the humerus to the right angle. Traction outward is commenced as soon as the humerus is half-way up, and is steadily and quietly, but firmly, continued, at the same time gently rotating the humerus outward; in other words, drawing the arm out of the side, and taking the hand and forearm up in the air, keeping the elbow at a right angle all the time. If the head of the humerus does not travel from beneath the coracoid (in the case of subcoracoid dislocation), the surgeon places his own feet nearer the patient, and while steadily pulling, falls away from the patient, thus bringing his own weight to assist traction, and in some obstinate cases slowly rocking the humerus up and down, or from side to side, to tire the powerful muscles which are resisting, chiefly, of course, the deltoid and pectoralis major. In most ordinary cases the head of the bone is observed to be now in the glenoid cavity, and on account of the steady continuous traction the head goes in without snap or jerk. If the head is not reduced by this time, rotation outward is continued until locking occurs. Rotation inward now immediately puts the humerus right; traction is at once stopped, and the surgeon slings the reduced arm to the patient’s side, keeping the hand high. If this method is applied very slowly and thoroughly, so little pain is caused that chloroform is rarely required to relax the resisting muscles.

The writer generally keeps up a running conversation with the patient during the manipulation; this serves to distract his attention, and cause involuntary relaxation of the muscles. Chloroform is occasionally required, not on account of the size of the muscles, but in highly strung, nervous men and women, who will not bear even slight discomfort, still less actual pain. If an anesthetic has been administered, the scapula is fixed in the same manner, the patient, of course, now lying down; the same traction and manipulation is gone through, but very little of each is then required. (Altering “left” to “right” and “front” to “back” in the above description will, of course, apply to dislocation of the left shoulder.)

Résumé.—Fix scapula; abduct arm, elbow being at a right angle, and apply traction; rotate humerus outward, add weight to traction if reduction obstinate, and rock humerus to still further tire the muscles if the patient is powerful, and rotate outward until locking occurs; rotate inward; slang hand to opposite shoulder.

During the last four years it has only been necessary to administer chloroform once in a recent dislocation, and the more familiar one becomes with the above method, the less frequently will an anesthetic be found necessary.

**GASTROPLICATION FOR DILATED STOMACH.**

Horrocks (Annals of Surgery, September, 1899) reports in detail a case of gastroplication for dilated stomach due to an old ulcer which was placed near the pylorus. This ulcer, during its early stages, possibly caused spasmodic stricture of the pylorus when the stomach emptied itself. Later the fixation of the pylorus caused a difficulty in emptying the stomach. It was evident that the increase in size of the stomach and the thinning of its walls were important factors in keeping up the dilatation. Mr. Barker, in such cases, speaks strongly in favor of posterior gastroenterostomy, and condemns gastrorrhaphy as unscientific. This may be true where there is a permanent stricture of the pylorus, but where the stricture is only temporary the lessening of the stomach cavity greatly alleviates the condition. The patient did well after the operation, and for a time the pain and sickness disappeared.

A month after the operation the old trouble returned; the swelling of the dilated stomach could be easily felt to the left of the scar. On considering the case, it seemed probable that the stitches holding up the stomach had given way, and that the left end of the stomach was still in a dilated condition. The pyloric part of the stomach was fixed to the abdominal wall. About this time a case was published in The Lancet by Mr. Moynihan, and the various methods of gastric suture discussed. By vertical sutures with silk he had obtained a good result. As the patient was still moribund, and had received benefit immediately after the first operation, it was proposed that the abdomen should be again opened and the stomach stitched with silk thread.
On April 20 a vertical incision was made to the left of the scar of the first operation, and the abdomen opened. The stomach was found dilated towards its cardiac end, the pyloric part being adherent to the abdominal wall. The dilated part was drawn forward and six silk sutures put vertically in and out through the muscular and peritoneal walls of the stomach. The sutures were then tightened and a few additional Lembert stitches added, to give increased security. Patient did well after the operation; the wound healed without trouble. She was discharged, and has since continued in a much better state of health. Her weight when she left the hospital was six and a half stones. She is now able to take any food without pain, and has had no attacks of vomiting. The swelling of the stomach cannot be felt.

The failure of the first operation was due to the catgut sutures, which were not sufficiently lasting; and the method of holding in the stomach wall with the folds parallel to the lesser curvature is not so satisfactory as the later proceeding. The weak state of the patient during the first operation made the stitching process a somewhat hurried one. In the second operation Mr. Bennett's method was employed, and certainly gave better results.

It seems reasonable in cases of dilatation of the stomach, when lavage, diet, and medical treatment have had a fair trial, if the dilatation still continues, that an exploratory abdominal incision should be made, and some attempt made to remove the cause of the dilatation.

Directions for the Sterilization of Catheters and Bougies.

Nicoll gives the following directions for the sterilization of catheters and bougies:

Bougies.—Gum-elastic bougies will not bear heating to a temperature sufficient for sterilization. Soaking for fifteen minutes in carbolic acid solution 1 in 20, for half an hour in 1 in 40, or for an hour in perchorlde of mercury 1 in 1000, renders the surface so sticky that the towel adheres in the process of drying, and the bougie becomes covered with fluff. After several soakings the surface becomes permanently dull and sticky and unfit for use. Dr. Schimmelbusch says that "a smooth bougie or catheter can mechanically be made externally free from germs by rubbing it with a piece of sterilized gauze and warm water." To test this a series of six gum-elastic bougies in use from six to eighteen months, after being employed in cases of stricture, were washed with tepid water and soap, rinsed in cold running water, and dried with thorough light friction with sterilized gauze. They were then rubbed on the surface of acid and alkaline agar tubes. In one case colonies of an unidentified coccus appeared, in another a patch of penicillium. The other ten tubes remained sterile. Six bougies soiled with pus were similarly treated; all the tubes remained sterile. In other experiments instead of the gauze an ordinary towel fresh from the laundry was used, and similar results were obtained. It appears, therefore, that antiseptic solutions which rapidly destroy instruments are unnecessary for sterilization.

Catheters.—Red rubber catheters (Jacques) may be sterilized by boiling or steaming, or may be soaked for months in carbolic solution (1 in 20) or perchloride of mercury (1 in 1000) without damage. A rubber catheter may be used daily for six months without becoming unfit for use, if washed every day with hot water and soap, and put to soak in carbolic lotion for the remainder of the twenty-four hours. But there are certain red rubber catheters which rapidly deteriorate under repeated boiling, and all rubber catheters ultimately do so. Prolonged and repeated soaking in antiseptics has little effect. By experiments the writer has proved that rubber catheters, boiled, steamed, or soaked for four hours in the lotsions mentioned, are rendered sterile internally and externally. But gum-elastic catheters, like bougies, will not stand the lengthened and repeated soaking necessary for sterilization. There is no entirely reliable method. For practice the writer has formulated the following rules:

1. Avoid as far as possible the employment of catheters. In cases of stricture it can only be very exceptionally that a catheter is called for. Bougies, which are readily sterilized, will do all that is necessary. 2. Where a catheter must be employed, use where possible a red rubber Jacques catheter in preference to a gum-elastic. In retention from atony, spinal paralysis, reflex nervous effects, and other causes, and in many cases of prostatic retention, the former answers as well, and is as readily sterilized by boiling or immersion in an antiseptic solution as is a metal catheter. 3. Where the red rubber fails to pass, the use of metal catheters, especially by the patient, does not commend itself as free from risk of injury. Gum-elastic
catheters must therefore be used. If the urine is very septic the writer destroys the catheters used. If the urine is not very purulent or offensive, he washes the catheters externally with soap and water, and then with antiseptic solutions, which is followed by internal steaming. Those that survive he retains. When the regular use of a gum-elastic catheter is necessary, the patient is supplied with a catheter with a well-finished interior. After use he thoroughly washes it, holds it under the tap for a few minutes, and lays it aside in boric acid, weak perchloride, or other weak antiseptic. This only offers a reasonable chance of asepsis, but it is useless to expect an average patient to carry out more elaborate plans. The writer has had glass tubes constructed, which are filled with the antiseptic solution, in which the catheter is placed after use. The solution varies in strength according to the kind of catheter; for gum-elastic catheters it must be weak, red rubber catheters will stand anything.

TETANUS TREATED WITH CARBOLIC ACID.

Woods (New York Medical Journal, September, 1899) was called to see a boy, aged twelve years, who had been wounded by a sharp nail which had penetrated about half an inch into the sole of his foot. Ten days later there was a stiffness of the muscles of the neck and spine. The disease was rapidly progressive. The general symptoms were attended with dyspnea and opisthotonos.

The place of injury was freely opened, and a dark tarry substance (altered blood) was scraped out. The foot was then soaked in a weak solution of carbolic acid and warm water for about half an hour.

As it was impossible for the patient to swallow, ten minims of a ten-per-cent solution of carbolic acid was used hypodermically; fifteen minutes thereafter twenty minims was injected; and fifteen minutes after the second injection thirty minims was used. Thirty minims was continued throughout the day every half-hour with half a grain of cannabis indica; at night the cannabis indica was discontinued, the pupils of the eyes being at this time very contracted. The carbolic acid solution was administered through the night, according to circumstances. If comparatively quiet, he was not disturbed, but when the interval was prolonged the dose was increased to a drachm hypodermically. There was considerable amelioration in the spasms on the second day, and the solution of carbolic acid was only administered hypodermically every two hours in half-drachm doses of a ten-per-cent solution. This treatment was kept up until the morning of the third day, when he could not swallow. Then a drachm of the solution in glycerin was administered every three hours until the spasms ceased. After the spasms ceased a drachm three times a day was given, and gradually diminished to half a drachm three times a day and kept up until all rigidity had left. Up to the third day the patient was nourished through the bowels with milk, eggs, and brandy. On the afternoon of the third day he slept for two hours, seemed refreshed, and said he felt better. From this time on he continued to improve, but the rigidity did not entirely leave him for three weeks after the attack. When he began to relax, his bowels were freely moved and his kidneys acted profusely. His urine soon after the carbolic acid was administered had the characteristic odor of the drug; and the smoky appearance was manifest on the second day. No perceptible irritation of the kidneys or bladder followed, and no permanent pernicious sequelae. He was weak and generally debilitated by the attack, but soon recuperated, and is now to all appearances perfectly well.

Reviews.

This book is illustrative of the fact that the practical physician can at times acquaint himself thoroughly with classical literature and utilize the knowledge which he gains in such a way that he is able to decorate a rather unattractive subject so as to make it pleasant reading. The design of the book, as the author tells us in his preface, is "not so much to offer an empirical, scientific consideration of human passion, as a philosophical study of love and its relationship to such psychical as well as physiological phenomena with which the most exalted sentiment of sexual attraction is closely allied." We have already stated that Dr. Butler has succeeded in presenting his subject in such a way that it is not offensive, but that he has gotten very much nearer an analysis of the subject under consideration is doubtful; indeed, we do not believe he expected to solve the riddle. The book is of interest if for no other reason than
that it brings together many references to classical literature which bear upon the subject under discussion.

In a small octavo of 400 pages, Dr. Malsbary has presented for the use of students a condensed treatise upon the practice of medicine which is very evidently a compilation of the principal facts stated in larger works on this subject. It seems to be a fairly accurate condensed handbook, and so far as it goes, reliable. In a subject such as the practice of medicine, however, we believe it is necessary for every student to possess one of the standard works upon this subject, since it is only by reading complete and exhaustive descriptions of a disease, as it is met with in clinical medicine, that he will get a clear insight into the cases which he will meet in future practice.

MEDICAL NEWS VISITING LIST.

Year after year we have the pleasure of noticing the appearance of this exceedingly convenient and useful list. It comes out in four forms, namely, weekly, and dated for thirty patients; monthly, undated, for 120 patients a month; perpetual, undated, for thirty patients weekly per year; and perpetual, undated, for sixty patients weekly per year. We believe that any one of these forms will be found very useful to the practitioner, according to the size of his practice. The Visiting List appears in a wallet-shaped book accompanied with a pocket-pencil and rubber, and is made of seal-grain leather. Its cost is $1.25, or with a thumb-letter index, 25 cents extra. It contains useful information in regard to the ligation of blood-vessels, with an accompanying diagram, tables of doses, and other useful facts.

ORGANIC MATERIA MEDICA AND PHARMACOGNOSY.

Several years ago we took pleasure in reviewing the first edition of this excellent book from the pen of Professor Sayre. The volume describes the botanical and physical characteristics, sources, constituents, pharmacopoeial preparations, and the insects which are injurious to drugs. It also takes up for consideration Pharmacal Botany, and this second edition contains histological and microtechnical tests by William C. Stevens, the Professor of Botany in the University of Kansas, and a fellow worker with Professor Sayre. The volume is very profusely illustrated, most of the illustrations being made from original drawings. It is emphatically one which is intended for the student of pharmacy rather than for the student of medicine, as practically no definite information is given concerning the subject of therapeutics. As a book for pharmacal students it is to be most highly recommended, for its subject matter is exceedingly good, and the publishers have gotten it out in a way which is attractive to the eye and which makes it easy to study.

A SYSTEM OF DISEASES OF THE EYE.

Within the last few years we have reviewed, as they appeared, the first three volumes of this encyclopedic work upon diseases of the eye—volumes which contain an immense amount of useful information, and articles which as a rule are of very great individual value. The ability of the editors and the skill with which they have selected their contributors is an earnest of the quality of the text, and the illustrations which the present volume contains are worthy of the subject-matter. Of the more important articles in this fourth volume we make mention of that on Anomalies of the Motor Apparatus of the Eyes, by Professor Landolt, of Paris; Diseases of the Cornea, by Professor Nuel, of Liege, Belgium; and Diseases of the Lens, by Prof. William F. Norris, of Philadelphia. Another very important article is that of Haab, of Zurich, upon Ocular Lesions Dependent upon Diseases in the Circulatory System; while Mr. Swanzy writes upon Eye Diseases and Eye Symptoms in Their Relation to Organic Diseases of the Brain and Spinal Cord. Another article of very considerable interest is that of Professor De Schweinitz, upon the Toxic Amblyopias, and that of Parinaud upon the Ocular Manifestations of Hysteria. In addition to the valuable information which these pages contain in the text, copious bibliographical foot-notes are added to the articles.
with the fact that all the articles are written from the standpoint of the clinician rather than that of the laboratory investigator, and Professor Lang and Mr. Jonathan Hutchinson speak in a way which indicates that the opinions which they express are derived from close personal study of the disease. Not only because the authors are so prominent, but also because the subjects with which they deal are so interesting, the present volume is to be considered one of the best in the series, and this is saying much in its praise.

CLINICAL LECTURES UPON NEUASTHENIA. By James D. Savill, M.D.

This is a small volume of 144 pages, in which Dr. Savill discusses the clinical aspect of neurasthenia in five lectures, all of which show that he has intimate knowledge of the condition of which he speaks. As we have already reviewed the English edition of this book some months ago, it is not necessary for us at this time to say anything further concerning it, other than to indicate that it may be obtained of an American publisher.

Sixth Edition, Revised and Enlarged.

We are told in the preface that this little manual is intended as a syllabus for the laboratory. It is so small that it can be readily carried in the pocket, and gives all the necessary information for the qualitative and quantitative estimation of the contents of the various fluids named in its title, and for the estimation of poisons which ordinarily gain access to the human body. In order to make the use of the manual still more readily carried out, illustrations are added whenever it is necessary to indicate the form of apparatus which the student should employ. The fact that the little volume has reached its sixth edition indicates that it meets the needs of a considerable number of students.

AN ATLAS OF THE BACTERIA PATHOGENIC TO MAN. By Samuel G. Shattuck, F.R.C.S. With an Introductory Chapter on Bacteriology by W. W. Babcock, M.D.

The design of this little book, of less than a hundred pages, is to provide the practitioner with descriptions of the morphology and microscopic examination of the pathogenic microorganisms which infect man. The plates and the text accompanying them are taken from the last issue of the Medical Annual of England, which we have fre-
REVIEW.

To those who have done work in medical literature Neale's Digest has been a close companion, and while the publication of the Index Medicus and the splendid catalogue of the Surgeon-General's Office at Washington has provided us with first-rate reference works, it is nevertheless a fact that Neale's Digest still fills the niche made for it by its scholarly editor years ago. It is with much pleasure, therefore, that we find that Dr. Neale has continued his excellent work, and has presented the profession with this valuable summary of literature covering the period since his last supplement was published. The present volume is an octavo of nearly 300 pages, arranged on exactly the same plan as its predecessors.

This book, which we have had pleasure in reviewing before in the Therapeutic Gazette, has reached a third edition within less than six years after its first publication. The present volume may be considered to be the most exhaustive work upon medical diagnosis in the English language, as it covers nearly 1200 pages. The fact that it is written by an able clinician of wide experience, with clinical instinct, is a guarantee that its contents are well worthy of the favor which it has already re-

ceived. The present edition is much larger than its predecessor, and contains a great number of colored plates and illustrations which successfully elucidate the author's text. Dr. Musser has been fortunate in having obtained a number of the younger workers in the various branches of medical diagnosis to revise and rewrite certain chapters, as, for example, that upon the Eye, the Sputum, and Nervous Diseases. Certainly no one can claim that anything which is of any importance has been omitted from these pages, and while a few old friends are to be found amongst the illustrations, they are always used to a purpose, and the great majority of them are original.

We can cordially recommend this volume, and feel sure that the reader will find in its pages any information which he may seek, as it deals with bacteriology in its relation to diagnosis, and every collateral science, microscopic and otherwise, which is needed in the determination of the disease from which a patient may be suffering.

Dr. Kyle's volume is one of 650 pages, copiously illustrated with lithographs, and in black and white pictures, and it is a noteworthy fact that most of the lithographs are exceedingly well executed. We do not remember having seen any illustrations of pathological conditions of the larynx and pharynx which seem so true to nature and so typical as the ones with which the author has improved his descriptions in the text. Another point which is of interest in connection with the publication of this book is that the author not only speaks from the standpoint of a clinical laryngologist, but also from that of a practical pathologist, and his experience as a teacher of pathology at one time in the Jefferson Medical College, and in maintaining a private pathological laboratory, has enabled him to approach his subject from a clinical and pathological standpoint, thereby making a very valuable combination. The third point of interest is that Dr. Kyle is one of those specialists who recognize that it is necessary that the patient's general condition shall always be considered when local conditions in the nose and throat are under treatment. Too often at the present day, when students on getting their degrees immediately become specialists, the specialist overlooks the general systemic condition of his patient,
and takes such a narrow view that his patients suffer in consequence. This, however, is not the case with Dr. Kyle and his book. One is impressed all through its pages with the fact that a healthy larynx cannot exist in an unhealthy body.

Still another reason why we think this book can be cordially recommended to the general practitioner is the fact that it is written in such a way as to be useful to this individual. Prescriptions illustrating the application of drugs to various diseased conditions are often given, and the text is written in a lucid manner, in which technical terms, when employed, are clearly explained. Not only do we believe that the book can be possessed with advantage by the specialist, but we can state to those general medical practitioners who read our pages that in it they will find a most valuable aid which will enable them to relieve many of the minor disorders of the upper respiratory passages.

We note with interest that Dr. Kyle urges upon practitioners the use of antitoxin in the treatment of diphtheria, and more important still, that he strongly advises large doses of it in the early stages of the disease, which doses are to be repeated if it does not readily yield to the first injection.

It is not often that we feel so favorably impressed with a book that we can most cordially recommend it, but in this case we can certainly do so both to the specialist and general practitioner.

ON THE PREVENTION OF EYE ACCIDENTS OCCURRING IN TRADES. By Simeon Snell.

Mr. Simeon Snell has published his address delivered at the opening of the Section of Ophthalmology at the annual meeting of the British Medical Association, at Portsmouth, August, 1899, in the form of an admirably printed and illustrated pamphlet, which should be in the hands not only of ophthalmic surgeons who are likely to meet with the various accidents which occur in trades, but also in the hands of overseers, superintendents, and managers of factories and mills which employ large numbers of iron and steel workers. Mr. Snell is strongly of the opinion that many of the eye accidents associated with trades are preventable, provided always the men are required to employ proper protection for their eyes, and that the men themselves are properly arranged at their work. The best protector appears to be made of gauze wire, especially if galvanized iron wire or aluminum wire is used. Netting of this character made into protectors covers the eyes and the adjacent parts, the whole arrangement, according to the author's pattern, somewhat resembling the shield which surgeons occasionally use after cataract extractions. The brochure is full of instructive information, statistics, and suggestions.

O. R. de S.

Correspondence.

LONDON LETTER.

BY RAYMOND CRAWFURD, M.A., M.D. OXON., M.R.C.P.
LOND.

We are now embarked on a new medical year. The schools and the medical societies have again resumed operations. However, the subject that is necessarily uppermost in every mind is the war in South Africa; in its medical aspect there is special cause for anxiety. The demand of recent years for commissions in the Royal Army Medical Corps has been so insufficient, that grave apprehension has been felt of its competency to deal with an extensive call. It was hoped that the granting of military rank and the formation of a definite corps would increase the popularity of the service, but up to date this has certainly not been the case. We fancy that the cause lies deeper than this, in the nature of the British youth. If the doors of the Temple of Janus were never closed, there would be no lack of eager competition; but in time of peace the almost exclusive care of venereal disease, without the gilding of even commercial advantage, fails to charm. But happily the defect carries its own antidote with it, and the first sound of battle has called up a host of civilian volunteers 'far beyond the requirements of the present grave crisis. Even the elders have caught the war fever, and Sir William MacCormac, President of the College of Surgeons, and Mr. Frederick Treves—perhaps the leader of surgical practice in London—and many others have volunteered for the front. American sympathy for the righteous cause in which we are fighting has aroused very lively satisfaction throughout this country.

I would call attention to arrangements that have been made in London to meet the increasing demand of foreign students for attendance at the London medical schools.
Nine of the leading schools have agreed on the issue of a ticket admitting qualified students to the practice of their hospitals. A fee of seven guineas is asked for three months, and of ten guineas for six months, and for any longer period at the rate of five guineas for each additional six months. The cards and full particulars may be obtained on application to the "Honorary Secretary, West Wing, Examination Hall, Victoria Embankment, W. C." For obvious reasons these facilities are not extended to unqualified students, and they can only avail themselves of hospital practice on terms that have been arranged by the hospitals individually.

Dr. Ewart is now advocating the prebathing treatment of heart disease by inhalation of carbonic acid gas, and the uses of the inhalation in cardiac dyspnea and in anginoid pain. At first sight this appears veritable homeopathy. It may be remembered that in a former letter I mentioned the application of this method of treatment to cases of leucocythemia. Ewart maintains that this treatment brings within the scope of Nauheim therapeutics a considerable number of cases that otherwise would be set down as unfruitful; indeed, he attributes much of the efficacy of the Nauheim bath treatment to the incidental inhalation of carbonic acid gas. Whereas balnear treatment exercises its greatest influence over the period of recuperation, the inhalation treatment is indicated in the stage of failing cardiac energy. Ewart lays it down that those cases will derive most benefit in which the elements of respiratory distress and cardiac pain predominate. Like many other drugs that in large doses possess a toxic and baneful effect, carbonic acid gas has in lesser doses an active physiological effect. It would seem that none of the carbonic acid gas inhaled passes directly into the blood-stream, but by raising the partial pressure of that gas in the lung prevents the liberation of some portion of the same gas already in the blood. Short of the asphyxial state induced by large doses of an irrepressible gas, Ewart enumerates the following as the chief physiological effects of smaller doses of carbonic acid gas: inhaled experimentally in moderate concentration: (1) a feeling of internal warmth, and after a time some flushings; (2) a strong desire to breathe, and particularly to breathe out; (3) an excited state of the circulation, which may amount to throbbing or palpitation; (4) a slight giddiness and headache supervening after a while in some susceptible subjects; (5) general anesthesia is not brought about by moderate inhalations; (6) cutaneous anesthesia has not been obtained as a result of the inhalation, but only by the local action of the gas upon the skin. Side by side with these effects of inhalation of carbonic acid gas on the healthy subject, Ewart sets the observations of its effect on patients with cardiac symptoms. The subjective effects are: (1) Rapid diminution or cessation of cardiac distress or pain; (2) a feeling of increased freedom of respiration. The objective effects are: (3) a visible increase in the depth of respiration; (4) a marked improvement of the pulse; (5) an obvious improvement both in the complexion and expression of more than transitory duration; (6) by systematic repetition progressive improvement in the patient's general condition, as well as in the cardiac and respiratory functions. Thus it will be seen that the direct effect upon the cardiovascular system is reinforced by the greater range of respiratory movements, which so to say open up wider channels by which the blood may find its way through the lungs.

In the discussion that ensued upon the paper Dr. Barr dealt somewhat severely with Ewart's views, on the ground that the tension of carbonic acid gas in the blood is so vastly higher than that of carbonic acid gas in the atmosphere that only an increase of asphyxial amount in the atmosphere could lead to absorption into the blood. However much one may disagree with Ewart's conclusions, one cannot accept the validity of this argument. In the first place, Ewart distinctly asserts that the effects are due not to increased absorption, but to decreased decarbonization; and it is self-evident that however slight the increase of partial pressure of carbonic acid gas in the atmosphere, there will be a parallel decrease of blood decarbonization, which may produce marked therapeutic effects. This same fallacy underlay the whole of Dr. Barr's criticism, which may therefore be set aside as not refuting the theory. We do, however, agree with him that more evidence is necessary before the inhalation treatment of failing heart should be admitted within the pale of practical therapeutics.

Furneaux Jordan read an interesting paper to the British Gynecological Society on the after-results of forty-three cases of removal of both appendages for disease, and on twenty-four operations for myomata of the uterus. From the former set of statistics he
finds uniformly good results in the relief of inflammatory diseases. The severity of the artificial menopause is much more marked in young women. Furneaux Jordan has not paid attention to the blood changes incident to the artificial menopause, which would have been of special interest in connection with some recent theories of the origin of chlorosis. He maintains that if the appendages are completely removed menstruation ceases entirely, and that the apparent exceptions are due to the difficulty in some cases of insuring complete removal; and that, granted removal be complete, hysterectomy will seldom be necessary. He draws attention to the high mortality of cases of pyosalpinx treated by abdominal section, and the frequency with which the drainage-tube leads to a weak spot in the scar. For these reasons he prefers the vaginal route for treatment of pyosalpinx whenever possible. In the second series of operations, Furneaux Jordan found that the disappearance of myomata was almost-invariable after removal of both appendages, and that the menopause was not so severe as when the operation was undertaken for inflammatory disease. This he attributes to the greater age of patients in the former instance, and this seems to be confirmed by the fact that the menopause due to hysterectomy was also less severe than the menopause due to removal of both appendages. Reviewing the whole question of the treatment of myomata, he formulates certain conclusions: That there are some cases in which no operation need be undertaken, and which can be satisfactorily treated by ergot and hydrastis, and rest, provided the patient be kept under observation; that in cases in which from loss of blood or other cause the patient's condition is so enfeebled that the major operation would endanger life, removal of the appendages should be preferred to hysterectomy—for large tumors, however, abdominal hysterectomy is the proper treatment; finally, that in cases where it is necessary to interfere with small myomata there is a choice of procedure—in a stout patient he would prefer vaginal hysterectomy, in one with a small vagina removal of the appendages.

Dr. Barkett, of Leeds, makes an interesting observation on the treatment of xeroderma by nitroglycerin. He obtained a large measure of relief in a very intractable and inveterate case in a child by the administration three times daily of one minim of liquor trinitrize, B. P. (nitroglycerin), with five minimis of nitrous ether. He suggests that the result is due to flushing the skin with blood by dilating the cutaneous capillaries, and instances the oily feel of the drunkard's skin similarly induced by the persistent imbibing of alcohol.

Jackson Clarke recommends an improved operation for hammer-toe. He excises the head of the bone by a curved dorsal incision over the prominent head of the second phalanx, opening the joint, dividing the lateral ligaments, and removing the head and a little more of the second phalanx. He reunites the divided expansion of the extensor tendons by a fine catgut stitch, and cuts away on the proximal side of the incision a portion of skin, including the site of the center of the corn previously removed by treatment. There is no tension, and therefore none of the pain incident to other methods of operation, when the wound is sutured with the toe in its straightened position.

PARIS LETTER.

One of the most important medical events of the last month in Paris was the session held by the Society of Medicine and Professional Hygiene, at which Dr. Calmette delivered a speech on the bubonic plague. Dr. Calmette is a comparatively young man, who has already published some important works on toxicology. He is specially known for his researches on antivenomous serum against snake-bites, and on the bacillus of the plague. Dr. Calmette is director of the Pasteur Institute at Lille, and was sent to Oporto to investigate the origin of the plague, and the means that can be employed to prevent its spreading.

In his speech Dr. Calmette described the work of Yersin, who discovered the microbe of the plague at about the same time as Kitasato. This microbe is characterized by the following points: It is short, slightly curved, is more highly colored at both ends than in the middle, is found in mild cases in the glands, and in the blood in severe cases. The cultures are more or less indifferent in aspect, with the exception of that in bouillon, in which after twenty-four hours there is a slight cloudy formation on the top of the tube, which disappears in the liquid on shaking it. After two or three days this cloudy formation settles in the bottom of the tube. Dr. Calmette insisted on the result of the inoculation of rats, mice, and
rodents generally. Yersin has already studied this question, and shown that an epidemic amongst rats and mice usually precedes its outbreak amongst men. Fleas have been shown to be the real cause of its rapid propagation, the former emigrating from the dead bodies onto animals of the same or of a different species. Another form of infection, such as the pulmonary one, which caused the death of Dr. Müller, of Vienna, shows there are sources of infection by ingestion, by the bite of fleas, and lastly by the lungs, from breathing air infected by desiccated sputa.

On arriving at Oporto Dr. Calmette tried to discover the real source of the infection. The bubonic plague was announced officially at Oporto on the 9th of August, but the first cases date from the 5th of June. Dr. Ricardo, the director of the hygienic service at Oporto, sent a report to the government on July 9, but for some unknown reason the latter was left unnoticed at the ministry. A careful examination of the arrivals in port showed no vessel coming directly from an infected region could be suspected, with the exception of the City of Cork, an English boat from London, which had brought from the latter port rice, Ceylon tea, jute from Calcutta, Bombay, and Mauritius. All these articles had been unloaded at least two weeks before the outbreak of the epidemic, and the last shipload was made up of wheat and codfish from New York. The first case was that of a stevedore who had helped unload the vessel, and who died in forty-eight hours. The second case occurred on the 7th of June, also a stevedore, who had helped unload the cargo of codfish.

The plague began to spread all over the city. Dr. Calmette gave a graphic description of the poorer quarters of Oporto, and showed how squalor and misery were to be incriminated in the spread of the epidemic. The patients seen by Dr. Calmette had generally reached the fifth day, and were in a comatose condition in most cases. The cases run their course in about seven to eight days, and at the time they were seen the symptoms observed beside the bubonic glands were those of a severe attack of typhoid fever. Great pain is noticed in the axilla and groin, especially on pressure; symptoms of myocarditis are soon perceived, also pulmonary edema and swelling of the mesenteric glands; in some cases large carbuncles with a black center form on the skin (black plague). In other cases the plague showed itself under the aspect of a case of typhoid pneumonia, with all the ordinary symptoms on auscultation, and brick-colored sputa containing large quantities of bacilli.

When he arrived at Oporto Dr. Calmette found nothing had been tried in the way of antitoxic serum, as the results of Yersin's labors in India had not been sufficiently clear to indicate a real efficacy.

A commission was appointed at the request of Dr. Calmette, which was asked to follow out the experiments. The first were carried out on the mouse and the monkey. Preventive inoculation was entirely successful, as well as curative inoculation. In some cases the injection had to be made into the venous circulation. Dr. Roux had been able to prepare some excellent serum by injecting into horses gradually increasing doses of bubonic toxins. It was this serum which Dr. Calmette had brought with him. Forty cubic centimeters was injected into the abdominal wall the first day, and as much the second day. The temperature went up after two hours from 39° to 39.8° or 40° C., then gradually went down after twelve to fifteen hours to 38°. If no further dose was given, the temperature rose again, and Dr. Calmette found the best way was to give small doses twice a day, as the bubonic plague is a form of septicemia, and the treatment differs slightly from that of lockjaw or diphtheria. A clear proof of the beneficial effect of the serum was given by the microscopic examination of the blood. On cultivating one drop the first day, thirty-two colonies were found; two only were found on the second, and none on the third day. The death-rate was considerably decreased, since instead of 43.4 per cent of mortality before the 3d of September, it went down to 13 per cent, once the treatment was rigorously applied. There were 104 cases, with fourteen deaths, five of which died in the twenty-four hours following admission; of these five, one died of tuberculous meningitis, one of puerperal fever, and one of bubonic meningitis, with ulcerations of the intestine. In some cases intravenous injections are indicated. All the employees of the hospital were vaccinated, without untoward effects, and none caught the plague. The effect of the vaccination does not last more than twenty days.

Dr. Calmette ended his report by indicating the reasons why the plague has not been stamped out completely. The disease had spread all over the city, and compulsory vaccination could not be applied.
The following are the best means calculated to stamp out any outbreak of the plague:

1. Complete isolation of all cases in a special hospital.

2. Destruction by fire of all houses in which cases have taken place.

3. Obligatory vaccination of all those who are or have come into contact with patients suffering from the plague.

4. Complete destruction of rats and mice by incineration.

PARIS LETTER NO. 2.

BY ROBERT HIRAM TURNER.

In the last Paris letter a promise was made to say a few words about the Bal de l'Internat, and to give an account of it, as we thought it would interest your readers. The Bal de l'Internat, such as it is, is of recent creation. Some eight or ten years ago the medical students flocked to the Bal Bullier, and the lord of misrule reigned supreme. Things have changed since then, and though more decorous, the proceedings are none the less very interesting.

This event took place on October 16. At noon in the Salle St. Jean of the Hôtel de Ville the internate question was read out to some 600 externes gathered to compete for the thirty-four places of interne advertised for the year. A description of this competition and the examinations that are passed has already been given in the Therapeutic Gazette.

The questions given this year were upon the upper maxillary nerve and the complications of diabetes mellitus. These questions were not appreciated very much, as about one-third of the students left the hall immediately. One must admit that a thorough knowledge of anatomy is necessary to be able to write ten to twelve pages of foolscap on the upper maxillary nerve. The questions not drawn were: Muscles of the Soft Palate, Abscess of the Brain, and Azygos Veins, Superior Vena Cava, and Tetanus.

The young men who took part in this examination were invited to a champagne supper by their seniors, and at about half-past ten the different salles de garde began to gather at the "Bullier." Many of your readers have heard or even seen this famous dancing hall, which vies in reputation with the celebrated Moulin Rouge situated on the Boulevard de Clichy. The first mentioned establishment, formerly known under the name of the "Closerie des Lilas," was once an enclosed garden, somewhat like the Jardin Mabille, and is situated on the Boulevard St. Michel, near the Observatoire. The writer of this letter, who happens to be the économie of the salle de garde of the Hôpital Boucicaut (i.e., the one chosen by his colleagues to see to the management of the salle de garde and to preserve the law), had stowed away his guests in eight or nine carriages, which took them to the Boulevard St. Michel. On arriving we found a huge crowd had gathered to see the fun. Some of the men had come in "tapissièrês," or chais a bancs (large carriages for the races). Each man had to show his ticket at the entrance, signed and countermarked by the head of each salle de garde. About twelve hundred invitations for the students had been sent out, and six hundred cards given to the female population. Marcille, one of Tillaux's aids, a stalwart young man with iron biceps, stood at the door ready to thrust forth any one not appearing in some eccentric fancy costume, while my colleague, Tissier, who has been these last two years the leading spirit in the organization of these balls, superintended and gave orders.

Once inside the scene was dazzling. Every conceivable sort of fancy dress had been put on, very few, however, being of a medical stamp. The Lariboisière Hospital, one of the largest in Paris, comprising a staff of nineteen house physicians and surgeons and seventy externes, had arranged one of the verandas running around the hall in a most artistic manner.

Some dancing was carried on in a rather desultory way until about twelve o'clock, when the great event of the ball—the cake walk, so to speak—took place. A certain number of hospitals had arranged their costumes in such a manner as to indicate some tableau vivant, and each salle de garde was to go around the hall twice, passing before a jury composed of five or six physicians and surgeons of the hospitals who had accepted invitations. The first prize was carried off by Lariboisière, which had taken as text, "The descent of Don Juan into the infernal regions." Don Juan was represented by Herrenschmidt, one of the internes of Lariboisière, surrounded by three or four damsels imploping his compassion. All the various
tortures of Sisyphus, Tantalus, and others were represented most admirably. The second prize went to La Charité, the triumph of Venus. The third prize was given to St. Antoine, the largest hospital in Paris, which figured a Japanese procession. The fourth prize went to Cochin, and the fifth to Boucicaut. We were a comparatively small number, but we were, with the exception of the Salpêtrière, representing the Spinal Cord, the only medical procession. We hardly think we need remind our readers that Mme. Boucicaut founded this hospital, so we figured the apotheosis of Madame Boucicaut.

First came a man dressed in a blue suit, like one of the liverymen of the Bon Marché, holding a large red umbrella over his head; then came a model in pasteboard of one of the hospital wards, with lights inside shining through the windows, a female figure dressed in green silk, painted over with pond lilies to represent the central fountain in the yard, and other figures representing the gardens; then the head of the salle de garde, accompanied by four acolytes dressed to represent the pavillons, with hats built in the form of ventilators; and largely a huge structure, on which a bust of Madame Boucicaut had been placed.

The ball was over at about four o’clock in the morning, and everybody went home more or less gay. During the whole progress of the ball I only saw one man intoxicated, which speaks after all pretty well for such a gathering; and besides, any attempt at indecorous behavior was frowned upon much more than in the olden time.

RELAPSE IN SCARLET FEVER.

To the Editor of the Therapeutic Gazette.

Sir: That relapse in scarlet fever is possible must be admitted, but the occurrence is rare and is scarcely mentioned by most writers on pediatrics.

On September 15, 1899, I was called to W. J., a delicate lad of nine years, and found a temperature of 103°, with rash and sore throat. As I did not see him till after dark it was impossible to determine the nature of the disease with certainty, but on the following morning it was apparent that the disease was scarlet fever, as an abundant rash with angina and involvement of cervical lymphatics demonstrated. The temperature after three days gradually subsided to the normal, and desquamation followed.

On October 4, nearly three weeks after the original attack, being recalled, I found a temperature of 105.5°, due apparently to indigestion, as he had been continuously overfed. Treatment seemed to exercise very little influence over the temperature. On the second day, with the temperature at the same point, slight tumefaction of the inframarylary glands was present, and on the third day, with the temperature still above 105°, a characteristic rash appeared on the lower extremities, which further observation showed to be a genuine scarlet rash. The angina returned, and every indication pointed to a genuine relapse from a reinfection. Desquamation occurred only once, as he was in the midst of it when the relapse occurred.

Holt speaks of relapse as a possibility, but no other writer with whom I am acquainted mentions it. It seems to me important that the possibility should be recognized, as the uncertainty as to the cause of the high temperature in this case was instantly dispelled by the recognition of the rash.

A. J. Rosenberry.

OAK PARK, ILL.

DILATATION OF THE STOMACH AND BOWEL.

To the Editor of the Therapeutic Gazette.

Sir: The tribute paid to gynecologists by Dr. Boardman Reed, of Philadelphia, in his article on stomach and bowel dilatation and displacement, is I think a doubtful one. On this point I do not, however, care to dwell, other than to say to the learned gentleman that he too may have a peculiar penchant for abdominal massaging.

I wish to say that the Doctor may be correct in a few things, but when he points to movable kidney as resulting from faulty modes of dress, the author cannot bring proof to support his assertion, for Drummond states that in the majority of cases there is a congenitally relaxed condition of the peritoneal attachments (mesonephron). Again, out of 300 or more cases 110 were traceable to the relaxation of abdominal walls which follows repeated pregnancies. Since the worthy Doctor has aimed a blow at the solar plexus of the gynecologist, let me ask him if he has massaged a displaced kidney back to its anatomical position and firmly fixed it. I presume he may
have caused many indolent, obstipated men and women to pay due homage to their alimentary canal through his efforts to stimulate peristaltic motion and assist nature.

If the good Doctor will turn to anatomy, he will there learn how useless it is to massage a dilated stomach when the transverse colon is compressed by its anatomical relations to the superior mesenteric vessels and nerves. On reflecting a dilated stomach it will be found that the transverse duodenum where it crosses the lumbar vertebra is itself crossed by the superior mesenteric vessels and nerves, which, compressing the duodenum at this point, is the great factor in bringing about stomach dilatation. Dr. Byron Robinson, one of the closest and most original thinkers and observers, has time and again called attention to this point, and has through post-mortem examination given absolute and undeniable proof of the correctness of his observation.

Faithfully yours,

J. A. McDonell, M.D.

MALARIAL HEMATURIA AND QUININE.

To the Editor of the Therapeutic Gazette.

SIR: During the last year the subject of malarial hemoglobinuria, especially in regard to the use of quinine in the treatment of the disease, has been discussed with much diversity of opinion in the leading medical journals, notably in the Therapeutic Gazette. The disease is quite common in the swamp countries of this State, where the pernicious forms of malaria are most prevalent. As the disease appeared here during 1898 and the early spring of 1899 it was marked with great abruptness in onset and duration, showing the type of the most intense infection, and unless combated with prompt and efficient treatment the mortality was exceedingly high. Last year was an exceedingly wet year, the wet weather lasting into the spring of 1899, and malarial diseases were much more prevalent and were of a much more malignant type. From February, 1898, to March, 1899, I treated eleven cases of malarial hemoglobinuria, with one death. Death will take place in from twelve to forty-eight hours in untreated cases, or in cases not efficiently treated. In this we have a disease which without efficient treatment means almost inevitable death, but with prompt treatment of the right kind most cases get well.

The patient I lost was a young lady, Miss B. J., aged sixteen, who had a relapse after about twenty-four hours of apyrexia and after the urine had been clear for forty-eight hours. The relapse took place with a paroxysm about twelve o'clock at night. The chill was soon followed by the voiding of large amounts of bloody-looking urine. Eight hours later I saw the patient, and found her much prostrated, owing to the fact that the previous attack, which had lasted about thirty-six hours, was severe, and the paroxysm she was just recovering from had also been very severe. Her temperature at 8 A.M. was 100° F.; pulse 125, small and compressible. There was moderate jaundice and profuse perspiration. At 9 A.M. she began to feel chilly, and soon was in a hard shake, which lasted about an hour, during which time there was much pain complained of in back, limbs, and bowels. Soon after the chill had ended the temperature registered 106° F., and there was great restlessness. A small amount of almost black urine was passed soon after the chill, and after this not more than a tablespoonful at a time was voided. About eighteen hours later the patient died in convulsions. Diuretics had no influence on the excretion of urine. This patient had received quinine during the first attack, with prompt arrest of the paroxysms and clearing up of the urine, but evidently the infection had not been broken but only retarded. The quinine was omitted too soon, the mother, who was the nurse, failing to continue it as I had prescribed (as she took a chill and neglected my patient).

Some of my cases were made mild by early treatment, and some of them had had the second or third paroxysm after the onset of hemoglobinuria when first seen. These cases all ran a severe course; death in some of them seemed inevitable, but fortunately prompt treatment soon arrested the disease.

In all my cases the hemoglobinuric attack had been preceded by one or more well defined malarial paroxysms, some of them having had the quotidian or tertian type for some weeks, and one patient had suffered from a double quotidian intermittent for about one week before the onset of hemoglobinuria.

In most of the cases just prior to the onset of hemoglobinuria the paroxysms come with more frequency. A quotidian is often con-
verted into a double quotidian or a triple quotidian, etc.

A patient, a girl of eleven years, was seized with a violent paroxysm, and at about the end of the chill a large amount of bloody-looking urine was voided. This characteristic brownish-red urine was voided at frequent intervals until about eight o'clock, when the urine cleared up to almost normal, and temperature went down to about 99° F., with profuse sweating. I saw the patient at 8 A.M., and about half an hour later she was taken with another severe chill. The temperature soon registered 104° F., the pulse very rapid and feeble; there was partial cyanosis, great restlessness, and the patient expressed a sense of impending death. Jaundice rapidly took place. Large amounts of almost black urine were voided at frequent intervals. Soon after the onset of the hemoglobinuria, before I saw the patient, the mother had administered a teaspoonful of nitrate of potash, and had also given calomel and turpentine freely, but with no results. I mention this because some physicians rely on this as the sole treatment, but I have never seen it do any good towards aborting the attack.) I at once began the use of stimulants, strychnine, digitalis, etc. Calomel in about five-grain doses was given every hour until bilious actions were produced. Enemata were given freely to hasten the action of bowels. Fortunately the stomach seemed in good condition to receive medicine, which is uncommon in these cases, consequently I relied on this organ for the absorption of quinine. Sixty grains of sulphate of quinine was dissolved in a solution of hydrochloric acid, and the full amount was consumed in about ten hours, by the end of which time there had been several actions from the bowels. The fever was almost gone, and the urine had cleared up to almost normal. Diuretics were given in addition to symptomatic treatment. There was no further paroxysm. The patient was very anemic for quite a time, and iron, quinine, and strychnine were given freely. In this case I gave more quinine in proportion to age than I ever gave before or have ever given since, and the results were more prompt than in any case where less of the drug was given. I gave this large amount because I well knew that another paroxysm meant death to the patient.

In severe cases of hemoglobinuria large proportions of the red blood corpuscles—perhaps one-fourth to one-third the entire amount in the body—are destroyed at one time, hence the great amount of hemoglobin set free in the blood, of which a large part is to be eliminated by the kidneys, perhaps some by the bowels, as I have seen large amounts of wine-colored fluid passed by the bowels after a paroxysm of malaria of other types, attended with great prostration. After the patient has suffered from a few paroxysms we have the type of the most intense anemia, the face and ears become colorless and waxy, and the rosary-tinted cheeks of other fevers are never to be seen. As we sometimes see hemoglobinuria from severe burns or from exposure to severe cold ushered in by a chill, is it not probable that the hemoglobinuria of malarial origin is also due to the destruction of red blood corpuscles? In each case we have hemoglobin set free in the blood in sufficient amount to give rise to hemoglobinuria. The jaundice is more probably hematojenous owing to the fact that there is such a great quantity of hemoglobin set free in the blood, a part of which is transformed into melanin and bile coloring matter. Also the jaundice presents the symptoms of the hematogenous other than the hepatogenous form. Lastly, the rapidity of its onset would prove that it is hematogenous in character, as it often occurs within six to ten hours after the first paroxysm. The symptoms of melanemia often appear within two hours after the chill. There are large amounts of bile produced by the liver and expelled by the bowels, if free purgation is obtained. There is great tendency to congestion of internal organs. In most cases there is nausea and vomiting during the first few days, so that drugs that are to be absorbed must be administered other than by the mouth.

I will not attempt to describe in detail all the complications and symptoms, but suffice it to say that my conclusions are that the disease in question is truly malarial in origin, that it presents more or less sharply defined malarial paroxysms, and that in most instances it can be arrested by prompt antimalarial combined with efficient symptomatic treatment. I draw my conclusions from the eleven cases I have treated and several cases I have known to be treated without quinine. All of those cases treated without quinine died.

I saw one case of hemoglobinuria or hematuria which was continuous, and had no paroxysms, the temperature being low, etc. This patient was treated without quinine and made a good recovery after four or five days.
It is probable that this was not malarial in origin, as it presented no paroxysms. There was no great urgency for prompt arrest of the disease, therefore tonics and restoratives were resorted to and the patient was treated on the expectant plan. I mention this case to show that all cases of hemorrhage from the kidneys are not identical, and that in drawing conclusions and decisions in regard to treatment these subjects should not be forgotten.

Suppression of urine is met with frequently in advanced cases where there is great destruction of blood and the consequent elimination of large amounts of hemoglobin by the kidneys. This is most probably caused by blocking up of the tubules and glomeruli of the kidneys by granules of hemoglobin. When this takes place to any marked degree I doubt if any case could recover.

As to treatment we have a specific in quinine if used in such cases as have come under my observation. Calomel in large doses, five to eight grains every one or two hours, should be given and aided by frequent large enemas. We should stimulate freely. If there is great restlessness morphine $\frac{1}{4}$ grain and atropine $\frac{1}{4}$ grain does good. If there is collapse or a tendency to it trinitrine $\frac{1}{8}$ $\text{grain}$ to $\frac{1}{4}$ $\text{grain}$ with atropine $\frac{1}{16}$ $\text{grain}$ is of great utility. The first named drug may be given every thirty minutes if required. Blistering over the stomach and hot turpentine stupes to the bowels are employed if called for. We should excite the flow of blood to surface by briskly rubbing with hot mustard solution. Diuretics should be given. Cold water externally is useful for prostrated high temperature. Unfortunately patients often cannot take and retain much cold water, as the stomach is nearly always irritated. Aside from the symptomatic treatment, our most hopeful aim is to arrest the progress of the disease, and, as we have such profound infection it takes larger doses of quinine to arrest the paroxysms. The drug is not promptly taken up and assimilated as in the milder forms of malaria, and for this reason we must give larger $\text{doses}$, and give them in such a way that they can most readily enter the system. Giving quinine in too small doses and in a way not to be readily taken up, and waiting too late to give it, have caused many to abandon its use. If they gave it too late to keep off the paroxysm, or did not give enough, it did no good and was consequently abandoned. The patient should be fully cinchonized at least three hours before the paroxysm is to come on, and as we do not know when to expect the paroxysm I make it a rule to begin its use as soon as I see the patient, if he is not then having a chill. It acts more promptly if given during the decline of the fever, but if we wait for the complete remission or intermission, as it may be, it is then too late to prevent the succeeding paroxysm in most cases. I use the sulphate or bisulphate of quinine dissolved in acid solution. If we use the bisulphate in saturated solution without the use of acid it is partly recrystallized by the alkalinity of the tissues and cannot be absorbed. I have used fifteen to twenty-five grains of the bisulphate in saturated solution without acid and failed to produce cinchonism. In severe cases I have given from thirty to sixty grains hypodermically within one or two hours, and when I used such amounts there was no return of the paroxysms. If we heavily cinchonize the patient the paroxysms stop and the urine clears up in from six to thirty-six hours, and in from eight to forty-eight hours the fever has disappeared. If there is an intermission in the hemoglobinuria at the end of the paroxysm, and we prevent the next paroxysm with quinine, there will be no return of it. I have given as much as 100 grains of quinine to an adult male with the happiest results. When I have used the most quinine I have had the most prompt results.

To those who believe the disease is produced by quinine I will say that some of my cases had not taken any quinine, while some of them had taken small amounts but not enough to arrest the disease.

J. WM. ROOP, M.D.

Snyder, Ark.

[It will be recalled by our readers that the Gazette has published much reliable literature showing that quinine must be used cautiously, if at all, in these cases.—En.]

Notes and Queries.

A WRONG DOSE

On page 748 of the November issue of the Therapeutic Gazette, in the second column, the dose of tincture of selentium and veratum viride is given at from 3 to 5 drachms. It should be drops. This error occurred in the journal which published the original article, and we regret that it was not discovered by us before.
